EMF EFFECTS ON MICROCIRCULATORY SYSTEM

CHIYOJI OHKUBO

RAD, WORLD HEALTH ORGANIZATION, GENEVA CH1211, SWITZERLAND

Abstract

The speaker reviews the importance of studying the effects of electromagnetic fields on microcirculatory system, especially in respect of possibility that vasculature may have direct and indirect role in interaction of static magnetic fields. It outlines the physiological importance of microcirculation and relatively new methods of evaluation technique in vivo and explains in details the local and/or whole body exposure effects of static magnetic field with range of 0.3–180 mT, power frequency electromagnetic fields with range of 0.1-30 mT and microwaves at 1.5 GHz with range 0.08 - 8 W/kg brain average SARs on microcirculatory systems in different tissues in experimental animals.

Introduction

The circulatory system is the transport system of the organism that supplies O₂, ions, hormones, and substances absorbed from the gastrointestinal tract to the tissues, and returns CO₂ to the lungs and other products of metabolism to the liver and kidneys. It also has a central role in the regulation of body temperature, and the distribution of the hormones and other agents that regulate tissue and cell function. The principal function of microcirculation is exchanging physiological substances between blood and tissues, and the compensatory adjustments should contribute to the efficacy of the exchange process: lumen dimensions, length, tortuosity, diameter of branch ratios, vascular density, wall thickness, vessel diameter (vasomotion), blood flow velocity, blood viscosity, intramicrovascular hematocrit, leukocyte-endothelial cell interaction and others.

Microcirculation consists of structurally and functionally differentiated small blood vessels: small muscular arteries, arterioles, metarterioles, capillaries, postcapillary venules, venules, and lymphatic capillaries. In the cutaneous microvascular beds, the connection between the arterioles and the venules is made by some thoroughfare channels including capillaries or arteriolar-venular shunts. In most vascular beds, the precapillary resistance vessels are responsible for the largest function of the resistance in a vascular bed, and hence are the major components that influence regional hemodynamics and total peripheral resistance. Smooth muscle cells are found in all of these except the blood capillaries and lymphatic capillaries. The blood capillary wall is composed of a single layer of endothelial cells. The lymphatic capillaries are composed of endothelium-lined vessels similar to blood capillaries. Fluid and protein that have extravasated from the blood capillaries partially enter the lymphatic capillaries and are transported via the lymphatic system back to the blood vascular system. Postcapillary venules play an important role in fluid and cellular exchange and are the major site of leukocyte migration into tissue spaces.

Rhythmical and spontaneous changes in both the diameter of arterioles and the volume and velocity of blood flow due to constriction and dilation of the vascular smooth muscle are known as vasomotion (1). The quantitative description of spontaneous arteriolar vasomotion requires data on frequency, amplitude, diameter, and branching order of the vessels observed. Fluid absorbed into lymphatic capillaries is passively transported through dynamic changes due to arteriolar vasomotion in cutaneous tissue. Frequency and amplitude of spontaneous vasomotion could play an important role in disease. In microangiopathies, lymphedema, and essential hypertension, altered patterns of arteriolar vasomotion could constitute an additional pathogenetic factor (2). Extracellular control of the smooth muscle cells is exerted through neurogenic, hormonal, local and myogenic mechanisms (3).

For evaluating EMF exposure effects on microcirculatory system, various microcirculatory preparations, e.g., rabbit ear chamber (REC) (4), dorsal skin fold chamber (DSC) in mice (5) and cranial window (CW) in mice and rats (6-7), have been used to observe and analyze microcirculation in our group. These preparations allow non-invasive, continuous measurement of hemodynamics, blood velocity, angiogenesis, metabolites, e.g., pH and pO₂, transport of molecules and particles, and cell to cell interactions in vivo (8).

Static fields

The REC offers the advantage of superior optical quality. Due to the longer duration of an individual measurement, we have exclusively utilized REC to investigate the effects of SMFs on microcirculation using microphotoelectric plethysmography (MPPG) monitoring system. REC is a round-table chamber made of acrylic resin for disk with an observing table and three holding pillars, a sustaining ring, and a glass window. The

methods for installation of REC and its availability to the bioelectromagnetic research have been published in detail (9-12). Blood Pressures (BPs) in a central artery contralateral to that of an ear lobe having the REC, fixed on the stage of the microscope, were monitored by a BP monitoring system.

1. Local exposure on the ear lobe to SMF (1.0 mT, 10 min) in conscious rabbits

Experimental Procedures: The SMF of 1.0 mT were generated by a C-shaped electromagnet device. An animal set on the observing stage of a microscope, laid prone in a holder without anesthesia. An intact central artery of the ear lobe fixed on an observing stage of the microscope was applied to analyzing the temporal changes of microcirculation in MPPG monitoring system. Two experimental procedures were randomly categorized: (1) sham exposure (CTL) and SMF exposure (SMF). MPPG profiles including DC levels and amplitudes of MPPG and/or BPs just before (pre-) exposure were compared with those during exposure and post-exposure.

Results: SMFs had a biphasic effect upon the microcirculatory system; when the vascular tone was low, the SMF induced vasoconstriction, and when it was high, the SMF induced vasodilation (9).

2. Whole-body exposure to SMF (5.5 mT, 30 min) in conscious rabbits

Experimental Procedures: The SMFs of 5.5 mT (Bmax) were generated by a doughnut-shaped annular electromagnet device. A rabbit in a holder was placed into the annular electromagnets. The measured magnetic flux densities were 5.0–5.5 mT in the trunk, 0.5–4.0 mT in the head, 1.0–4.0 mT in the throat, and <1.0 mT in the ear lobe, respectively. Two experimental procedures were randomly categorized: sham exposure (CTL) and SMF exposure (SMF). These values pre-exposure were compared with those during exposure and post-exposure.

Results: Comparing SMF with CTL, there were no significant changes in MPPG values throughout the experiment. For BPs, comparing SMF with CTL, there were no significant changes throughout the experimental period (13).

3. Local exposure on the ear lobe to SMF (1.0 mT, 10 min) in pharmacologically treated rabbits with REC

This study is attempted to demonstrate the vasoconstrictor effect as well as the vasodilating effect by local exposure on the cutaneous microcirculation within a REC under pharmacologically modified vascular tone. Based on the hypothesized effects, nor-adrenaline (NA) and acetylcholine (ACh) were chosen to enhance and reduce the vascular tone pharmacologically.

Experimental Procedures: Cutaneous microcirculation of REC exposed to SMF was studied under pharmacological treatment using MPPG method. NA and ACh were used for increase sympathetically and decrease parasympathetically in vascular tone, respectively.

Results: The temporal changes of MPPG profiles during and after exposure were quantitatively analyzed. In NA group, the vasoconstriction with reduced vasomotion was observed throughout the experimental period. In NA+SMF group, the vasoconstrictor effects with reduced vasomotion followed by NA infusion were significantly reduced. In contrast, in ACh group, the vasodilation with increased vasomotion was observed throughout the experimental period. In ACh+SMF group, however, the vasodilator effect with increased vasomotion followed by ACh infusion were significantly reduced. In mean amplitudes of MPPG between ACh+SMF and ACh groups, there were significant differences for up to 60 min after cessation of SMF exposure. In CTL group, there were no significant changes throughout the experimental period (11).

4. Local exposure on the ear lobe to SMF (1.0 mT, 30 min) in pharmacologically treated rabbits without REC

The purpose of this study is to elucidate the hypothesized homeostatic effects of SMF on BPs, and to show that it can alter the microcirculation in a cutaneous tissue and hence modify the BPs. This study was designed to investigate the effects of SMF on a Ca^{2+} channel blocker, nicardipine (NIC)-induced hypotension as well as a nitric oxide synthase (NOS) inhibitor, Nx-nitro-L-arginine methyl ester (L-NAME)- induced hypertension.

Experimental Procedures: The effects of SMF on BPs in rabbits were investigated under pharmacological treatment. Hypotensive and vasodilator actions were induced by NIC. Hypertensive and vasoconstrictor actions were induced by L-NAME.

Results: In NIC alone, the acute and intense vasodilation with increased vasomotion resulting in increases of both MPPG parameters was observed. In SMF + NIC, by contrast, the vasodilating effect with increased vasomotion following NIC injection was reduced. In mean amplitude between SMF+NIC and NIC, there was a significant difference during SMF exposure. In L-NAME alone, 10 min after L-NAME infusion, the vasoconstriction resulting in decreases of mean DC level was observed. In SMF + L-NAME, by contrast, the vasoconstrictor effect following L-NAME infusion was reduced. In mean amplitude between SMF + L-NAME and L-NAME, however, there were no significant differences throughout the experimental period. In NIC alone, BPs decreased from baseline immediately after NIC injection. In contrast, in SMF + NIC, the reduction of BPs was suppressed. In L-NAME alone, BPs gradually increased from baseline after L-NAME infusion. In contrast, in SMF + L-NAME, the elevation of BPs was suppressed during exposure and post-exposure (14).

5. Local exposure on the neck or pelvic to SMF (1.0-5.5 mT, 30 min) in pharmacologically treated rabbits

Experimental Procedures: Magnetic flux densities were up to 5.5 mT and the spatial magnetic gradient peaked in neck (carotid sinus baroreceptor) region at the level of 0.06 mT/mm. The duration of exposure was 30 min and the effects on BP were investigated up to 100 min post-exposure. BPs were pharmacologically modulated by norepinephrine (NE)-induced hypertension as well as an L-type voltage-gated Ca^{2+} channel blocker, nicardipine (NIC)-induced hypotension. Baroreflex sensitivity (BRS) was estimated from invasive recordings of systolic BP and pulse interval.

Results: Neck exposure to 5.5 mT significantly attenuated the pharmacologically induced vasoconstriction or vasodilation, and subsequently suppressed the increase or decrease in BP compared with sham exposure. In contrast, pelvic exposure to 5.5 mT did not significantly antagonized NE-elevated BP or NIC-reduced BP. The neck exposure to 5.5 mT has a biphasic and restorative effect on vascular tone and BP acting to normalize the tone and BP. The neck exposure to 5.5 mT caused a significant increase in BRS in NE-elevated BP compared with sham exposure. The buffering effects of the SMF on increased hemodynamic variability under NE-induced high vascular tone and NIC-induced low vascular tone might be, in part, dependent on baroreflex pathways, which could modulate NE-mediated response in conjunction with Ca^{2+} dynamics (15).

6. Whole-body exposure to SMFs (0.3, 1.0, and 10.0 mT, 10 min) in anesthetized mice

This study was designed to investigate the effects of SMFs for modulating the muscle capillary microcirculation under pentobarbital-induced hypnosis.

Experimental Procedures: SMFs were generated by a C-shaped electromagnet device. Muscle capillary microcirculation of mice exposed to SMFs (0.3, 1.0, and 10.0 mT, 10 min) was studied under pentobarbital anesthesia. FITC-labeled dextran was used for an in vivo fluorescent plasma marker of the muscle capillaries.

Results: Significant increases of the peak blood velocities by SMFs of at least 1.0 mT were observed, whereas those of the mean blood velocities were not. In CTL or SMF exposure at 0.3 mT, on the other hand, there were no significant changes throughout the experimental period within either of the peak blood velocities (16).

7. Whole-body exposure to SMF (10 or 25 mT, 12 weeks) in reserpine-induced hypotensive rats

This study investigated the interrelated antihypotensive effects of static magnetic fields (SMF) and plasma catecholamine levels in reserpine-induced hypotensive Wistar-Kyoto rats.

Experimental Procedures: Seven-week-old male rats were exposed to two different ranges of SMF intensities, 3.0-10 mT (Bmax) or 7.5-25 mT (Bmax) for 12 weeks. Six experimental groups of 10 animals each were examined: (1) no exposure with intraperitoneal (ip) saline injection (sham exposed control); (2) 10 mT SMF exposure with ip saline injection (10 mT); (3) 25 mT SMF exposure with ip saline injection (25 mT); (4) no exposure with ip reserpine injection (RES); (5) 10 mT SMF exposure with ip reserpine injection (10 mT + RES); (6) 25 mT SMF exposure with ip reserpine injection (25 mT + RES). Reserpine (5 mg/kg) was administered three times a week for 12 weeks, and 18 h after each injection, arterial blood pressure (BP), heart rate, skin blood flow, plasma nitric oxide metabolites, plasma catecholamine levels, and behavioural parameters of a functional observational battery (FOB) were monitored.

Results: The reserpine administration significantly decreased BP, reduced plasma norepinephrine (NE), increased the FOB hunched posture score and decreased the number of rearing events in the RES group, compared with the respective age-matched control group. Exposure to 25 mT, but not 10 mT, for 2-12 weeks significantly prevented the reserpine-induced decrease of BP in the 25 mT + RES group compared with the respective RES group. Moreover, exposure to 25 mT for 5 weeks partially suppressed the reserpine-induced NE reduction, but did not bring about a complete reversal of reserpine effects. NE levels for the 25 mT + RES group for 5 weeks were significantly higher compared with the RES group, but still lower compared with the control group. In addition, the FOB hunched posture score for the 25 mT + RES group was significantly lower and the number of rearing events was higher compared with the RES group, but these behavioural parameters did not revert to control levels. There were no significant differences in any of the physiological or behavioural parameters measured between the 10 mT + RES and RES groups, nor between the two different SMF groups and the control group (17).

8. Whole-body exposure to SMF (5.5 mT, 30 min) in pharmacologically induced hypertensive rabbits

The purpose of our study is to elucidate the hypothesized hypotensive or antipressor effects of SMFs, and to show that it can alter the microcirculation in a cutaneous tissue and hence normalize the BPs. More particularly, this study was designed to investigate the effects of SMF on pharmacologically induced hypertension via NA-mediated increases in sympathetic nerve activity, or a NOS inhibitor in vascular endothelial cells and/or neurons.

Experimental Procedures: Hypertensive and vasoconstrictor conditions were induced by NA or a NOS inhibitor, L-NAME. As a preliminary intensity-finding experiment using SMFs ranging 1.0–50.0 mT in NA-induced hypertension, whole-body exposure to SMFs under 5.5 mT did not significantly induce antipressor effects.

Results: In NA alone, just after NA infusion, the acute and intense vasoconstriction resulting in reduction of mean DC level of MPPG was observed. In SMF + NA, by contrast, the vasoconstrictor effect following NA infusion was antagonized. In L-NAME alone, the vasoconstriction resulting in decreases of mean DC level was observed. In SMF+L-NAME, the vasoconstrictor effect following L-NAME infusion was reduced. Comparing mean amplitude of MPPG between SMF+L-NAME and L-NAME; however, there were no significant differences throughout the experimental period. In NA alone, BPs increased from baseline after NA infusion. In contrast, in SMF + NA, the elevation of BPs was antagonized and hypotension was induced. After withdrawal of SMFs, there were significant differences between SMF+NA and NA in BPs. In L-NAME alone, BPs increased from baseline after L-NAME infusion. In contrast, in SMF + L-NAME, the elevation of BPs was suppressed during exposure and post-exposure. For plasma vasoactive substances, comparing between NA and SMF + NA in pre- and post-exposure, there were no significant changes in any catecholamines, angiotensin II and aldosterone levels (13).

9. Whole-body exposure to SMF (1, 5, 10 and 25 mT, 12 weeks) for genetically hypertensive rats

The purpose of our study is to elucidate the hypothesized antipressor effects of SMFs with mT levels on a genetically hypertensive animal.

Experimental Procedures 1: A SMF exposure device was composed of a pair of rectangular magnetic plates (strontium-ferrite) externally placed in parallel. Four types of SMF exposure devices with different magnetic flux densities were used. The mean flux densities in the center of a cage were ranging from 3.0 to 10.0 mT (Bmax) here referred to as SMF 10 mT and ranging from 8.0 to 25.0mT(Bmax) as SMF 25mT. Effects of SMFs on development of hypertension were investigated using young male stroke-resistant spontaneously hypertensive rats (SHRs) beginning at 7 weeks of age. SHRs were randomly assigned to two different exposure groups or an unexposed group. A rat in a cage with magnetic plates was exposed to either SMF continuously for 12 weeks, except during the short period of measuring BPs and heart rate and blood sampling. The BPs and heart rate in each rat were determined weekly using tail-cuff method.

Results 1: The changes of systolic BP with continuous exposure to either SMF for 12 weeks and with crossover exposure to SMF 25 mT for 6 weeks were indicated, as compared with sham exposed group. The rats exposed to SMFs displayed suppression and retardation in the development of systolic BP during 2–9 weeks. However, at least 1 week after crossover exposure for 6 weeks, significant differences between systolic BP disappeared. Similar suppressions of development of hypertension exposed to SMFs also occurred in diastolic BP during 5–6 weeks in SMF 10 mT and during 3–6 weeks in SMF 25 mT. Moreover, antipressor effects on mean BP were observed during 3–5 weeks in both SMFs. Exposure to SMFs for 5 weeks significantly reduced the concentrations of plasma angiotensin II and plasma aldosterone concentration, as compared with sham exposed group. There were no detectable effects of SMFs on the other measured vasoactive substances (renin activity, angiotensin I, arginine vasopressin and angiotensin I-converting enzyme concentrations) (18).

Experimental Procedures 2: Seven-week-old SHRs were exposed to three different ranges of SMF intensity, ranging from 0.3 to 1.0 mT (Bmax) here referred to as SMF 1 mT, ranging from 1.5 to 5.0 mT (Bmax) here referred to as SMF 5 mT, for 12 weeks and sham exposure. Arterial BP, heart rate, skin blood flow and plasma NO metabolites (NOx) and plasma catecholamine levels were monitored.

Results 2: SMF 5 mT, but not SMA 1 mT, significantly suppressed and retarded the early stage development of hypertension for several week, compared with the age matched, unexposed (sham exposed) control. Exposure to 5 mT resulted in reduced plasma NOx concentrations together with lower level of anigiotensin II and alsosteron in SHR (19).

10. Local-body exposure on the baroreceptor region to SMF (180 mT, 6 and 14 weeks) in genetically hypertensive rats

The purpose of our study is to elucidate the hypothesized antipressor effects of SMFs with mT levels on SHRs special regard to exposure region to the baroreceptor.

Experimental Procedures: This study investigated the combined effects of a moderate intensity SMF and a Ca^{2+} channel blocker, nicardipine in stroke-resistant SHRs. A disc-shaped permanent magnet or a dummy magnet was implanted in the vicinity adjacent to the left carotid sinus baroreceptor region in the neck of each rat. Five-week-old male rats were exposed to SMF intensity up to 180 mT (Bmax) with a peak spatial gradient of 133 mT/mm for 14 weeks. Four experimental groups of 14 animals each were examined: (1) sham exposure with intraperitoneal (ip) saline injection (control); (2) SMF exposure with ip saline injection (SMF); (3) sham exposure with ip nicardipine injection (NIC); (4) SMF exposure with ip nicardipine injection (SMF+NIC). Nicardipine (2 mg/kg ip) was administered three times a week for 14 weeks, and then 15 min after each injection, arterial blood pressure (BP), heart rate (HR), baroreflex sensitivity (BRS), skin blood flow (SBF), skin blood velocity (SBV), plasma nitric oxide (NO) metabolites (NOx), plasma catecholamine levels and behavioural parameters of a functional observational battery were monitored.

Results: The action of nicardipine significantly decreased BP, and increased HR, SBF, SBV, plasma epinephrine and nor-epinephrine in the NIC group compared with the control respective age-matched group without changing plasma NOx levels. Neck exposure to SMF alone for 5–8 weeks significantly suppressed or retarded the development of hypertension together with increased BRS in SMF group. Furthermore, the exposure to SMF for 1–8 weeks significantly promoted the nicardipine-induced BP decrease in the SMF+NIC group compared with the respective NIC group. Moreover, the SMF induced a significant increase in plasma NOx in the nicardipine induced hypotension. There were no significant differences in any of the physiological or behavioural parameters measured between the SMF+NIC and the NIC groups, nor between the SMF and the control groups (20-21).

Summary of Static Field Effects

Microcirculation and BPs were modulated by SMFs with mT levels in pharmacologically treated animals and genetically hypertensive animals. By contrast, these physiological parameters were not changed by SMFs in normal animals. Appreciable minimum level for modulating microcirculation and BPs was 1.0 mT in pharmacologically treated animals. For the minimum exposure duration of 1.0 mT, it took 10 min to change microcirculation and 30 min to modulate BPs in these animals. To induce antipressor effects of SMFs on pharmacologically induced hypertensive animals, the whole-body exposure to SMF of 5.5 mT for 30 min was needed. To induce antipressor effects of SMFs on genetically hypertensive animals, whole-body exposure to SMFs of 5.0 mT for at least 2 weeks was required.

The effects of SMFs in the mT range were mediated by antagonizing the action of biochemical substances, there by inducing homeostatic effects biphasically:

1. Suppression of an adrenergic neurotransmitter, NA-induced vasoconstriction, and hypertension
2. Suppression of a cholinergic neurotransmitter, ACh-induced vasodilation
3. Suppression of reserpine-induced hypotension and bradykinesia.
4. Suppression of an anesthetic agent, pentobarbital-induced decrease in the peak blood velocities
5. Suppression of a Ca²⁺ channel blocker, nicardipine-induced vasodilation and hypotension
6. Suppression of a NOS inhibitor, L-NAME-induced vasoconstriction and hypertension
7. Suppression of early BP elevation via inhibition of elevation of vasopressor hormones, Ang II and Ald
8. Suppression of delay BP elevation via the NO pathway and hormonal regulatory systems
9. Enhancement of nicardipine-induced antipressor effects in SHR which partially related to NOx activity

The effects of SMFs with mT levels on microcirculation and BPs obtained from different mammals would be used in possible explanation for the therapeutic effects on many ischemic diseases related to dysfunction in circulation and microcirculation. Furthermore, the SMFs might exert regulatory effects on BPs.

ELF EMFs

1. Whole body exposure effects to threshold levels of 50 Hz EMFs (0.3-30 mT, 30 min or 15 days) in mice

Whole body exposure effects to threshold levels of 50 Hz electromagnetic fields (3.0, 10.0, 30.0 mT for acute exposure and 0.3, 1.0, 3.0 mT for subchronic exposure) on intramicrovascular behaviour of leukocytes in the cutaneous microcirculation was evaluated by newly developed dorsal skin fold chamber (DSC) technique in mice under conscious conditions. The results indicated that the exposure intensity at 3.0 mT is a threshold level for increasing leukocyte adhesion to the endothelial walls. Effects of 50Hz electromagnetic fields (EMF) exposure on leukocyte are mainly performed *in vitro*, however, little information of these is available *in vivo* experiments. In order to investigate the acute and subchronic exposure effects of threshold levels of 50Hz EMF on leukocyte behaviour *in vivo* system, we measured the behaviour of intra-microvascular leukocytes in the cutaneous microcirculation in mice.

Experimental Procedures: Male mice (BALB/c) having the DSC were subjected to intravital-microscopic study. We have developed the DSC with non-metal materials of Duracon resin, which could not be physically affected by EMF exposure. For visualization of intra-microvascular leukocytes, fluorescent dye (rhodamine 6G; 0.3mg/kg, iv) was injected. The numbers of leukocyte rolling or adhering to the venular walls were measured by confocal laser microscopy and recorded into VCR and analyzed from the images. The magnetic flux densities used for the acute exposure (30 minutes) were controlled at 3, 10, 30 mT at the centre of animal body (n=10 each), respectively. For subchronic exposure study, mice were divided into 4 groups (n=10 each), i.e., exposure group with 50 Hz EMF at 0.3, 1.0 and 3.0 mT and control group with sham exposure. The 50Hz EMF exposure was intermittently performed everyday from 16:00 to 12:00(20hours/day) for 15 days. Plasma cytokine (IL-1 β , TNF- α) concentration was measured by ELISA.

Results: Acute Effects (3, 10, 30 mT, 30 min): A tendency to increase the adherent cell count of leukocytes due to the 50 Hz EMF exposure toward higher magnetic field intensity was recognized. Following the exposure at 30 mT, the counts of adherent cell was significantly higher than those obtained before exposure. Subchronic Effects (0.3, 1.0 and 3.0 mT, 15 days): Following subchronic exposure to 50Hz EMF, no significant changes in arteriolar blood flow velocity and diameter were noticed in both groups, however, statistically significant

increases ($p < 0.05$) in adherent leukocyte counts at 3.0 mT were noticed. There was no change in IL-1 β and TNF- α plasma levels between before and after exposures in any group. No noticeable changes in the adherent cell counts were observed between before and after sham exposures in the control group.

Conclusion: The results indicated that 50 Hz EMF exposure may influence cell to cell interaction between venular endothelial cells and leukocytes. Previous observations using human monocyte in *in vitro* system indicated that changes in cytokine profile of monocyte were induced by exposures of 50 Hz EMF. We hypothesize that 50 Hz EMF exposure effects on leukocyte and endothelial cell interaction due to change in cytokine levels, however, IL-1 β and TNF- α may not be involved in this phenomenon (5, 22-23).

2. Whole body exposure effects to 50Hz EMFs (3mT, 15 days) on mammary tumour proliferation in mice

The tumor vasculature consists of both vessels recruited from the pre-existing network from the angiogenic response of host vessels to cancer cells. In the process of cancer promotion, angiogenesis is one of the key issues to proliferate their cells into host tissue. We have intravital-microscopically found that 50Hz electromagnetic fields (EMF) as well as static magnetic field exposure (>1 mT) might modify the microvascular tone in rabbits under conscious conditions. If 50Hz EMF can affect on hemodynamic parameters of pre-existing microvasculature, 50Hz EMF may also affect on tumor vasculature or angiogenic process, hence, growth rate of tumor cells which implanted into the animals.

Experimental Procedures: Mammary tumour cells (MMT06562: MMT) were grafted into DSC. The area occupied by tumour tissue within a DSC was measured by PC image analysis with NIH image. Mice were divided into 2 groups ($n=10-12$ each), i.e., exposure group with 50 Hz EMF at 3 mT and control group with sham exposure. The 50Hz EMF exposure was intermittently performed everyday (22hours/day) for 15 days. Blood vessel diameter, blood flow velocity, adherent leukocyte counts to venular wall were evaluated by comparison between these values of pre- and post-exposure within group, or these of exposure group and control group.

Results: After MMT grafting, almost one week required to initiate the angiogenic response. During 2 weeks' whole body exposure to 3 mT, 50 Hz EMF, successive changes of angiogenesis including vascular density and growth of the tumor were compared with non-exposed control animals. The area occupied by tumor tissue within DSCs of the exposure group is smaller than its control group, however, no significant difference was found between them.

Conclusion: The results indicated that 50 Hz EMF exposure at 3 mT induced no effects on the mammary tumour cell proliferation in tumour bearing animals (24).

3. Whole body exposure effects to 50Hz EMFs (3mT, 15 days) with or without transient magnetic fields (7.4 kHz with 50 msec, 162 μ T) on brain tumour proliferation in SCID mice

This study evaluates whole body exposure effects to ELF-EMF with transient magnetic field on the implanted brain tumour growth and tumour microcirculation within a mice cranial window (CW).

Experimental Procedures: Male SCID (Severe combined immuno-deficiency) mice were used in this study. One week after installation of CW, the window was opened and a small piece of human glioma U87 tissue which grown in source mouse was implanted into the centre of CW. Then, mice were divided into two groups: exposure and sham group. In exposure group, mice were subchronically exposed to combination of 50 Hz EMF with repetitive transient magnetic fields (1 burst/s, 7.4 kHz waves with duration of 50 msec and peak magnet density of 162 μ T) for 15 days (15 hours/day: 7 p.m. to 10 a.m.) following tumour implantation. During and after the exposure, we measured the size of tumour, microcirculatory parameters of angiogenic vessels in the growing tumour by real-time confocal microscopy, and vascular permeability of rhodamine-labelled albumin using a photon counting system.

Results: Although tumour size increased markedly following implantation, tumour growth did not show any significant difference between the exposure group and control group. Tumour angiogenesis was also induced inside and around the tumour tissue, however, ELF-EMF with transient magnetic fields did not affect any of the microcirculatory parameters of these angiogenic vessels, for instance, vascular density, mean diameter and branched numbers of vessels.

Conclusion: No possible pathophysiological effect in the brain tumour microcirculation can be induced by the subchronic and combined exposures of 50 Hz (3 mT) and transient magnetic fields. The growth rate of implanted brain tumour tissue was not also affected by the present exposure conditions (6).

4. Whole body exposure effects to ELF EMFs (10, 16 and 50 Hz, 28 mT, 10 min) on cutaneous microcirculation in mice

Experimental Procedures: Three different ELF EMFs, e.g., 10, 16 and 50 Hz, were used in this study. Following caudal vein injection of FITC-dextran 250 kDa, the microvasculature (initial arteriole diameter of 45–80 μ m), was examined by intravital microscopy and video images were recorded. Measurements of blood vessel diameter within a DSC were continuously monitored for 33 min including pre-, during and post- exposure of ELF-EMF

and every 389 ms blood vessel diameter were calculated.

Results: During and post-exposure to 16 Hz EMF, arteriolar diameters increased significantly compared with the pre-exposure period, and the changes were larger during post-exposure. No noticeable changes in arteriolar diameters were obtained from exposure to sham, 10 Hz and 50 Hz EMFs.

Conclusion: This study indicates that frequency specific interaction may be evoked by ELF EMF (16 Hz), however, further research is needed to confirm this phenomenon (25).

RF EMFs

Local exposure to 1.5 GHz RF-EMF (0.08 - 35 W/kg brain average SARs, 10, 50, 80 min or 4 weeks) in rats

There is little information available about the exposure effects of EMF on cerebral microcirculation. In this study we developed a cranial window method for evaluating the exposure effects of EMF on the BBB function, hemodynamics of pial microcirculation and behaviour of intramicrovascular leukocytes by using an intravital microscopy in rats.

Experimental Procedures 1: In the monopole antenna experiment, the exposure system consisted of a small anechoic chamber and a monopole antenna. The head of each rat was positioned toward the central antenna and was locally exposed to 1,439MHz electromagnetic near-field TDMA (time division multiple access) signal for PDC (Personal Digital Cellular, Japanese cellular telephone standard) system. The degree of intensity of RF exposure was controlled by mean specific absorption rate (SAR) of the brain. The SAR values were 1, 4, and 8 W/kg for acute effect experiment, and 4 W/kg for sub-chronic effect experiment, respectively. The EMF exposure duration was 10 minutes for the acute exposure experiment and was 60 minutes everyday, 5 days a week for 4 weeks for the subchronic exposure experiment. The pial microcirculation including vascular diameters, plasma velocities, leukocyte behaviour and BBB-function within the cranial window was investigated by a fluorescence microscope equipped with an SIT camera.

Results 1: Acute Exposure Experiment: The values in the diameters and maximal plasma velocity of the pial venule of pre- and post-exposures did not significantly differ from each other for any SARs tested. Corresponding to the increase in SAR, the number of rolling leukocytes on the venular endothelia tended to decrease, however, no significant differences were recognized between the values for pre- and post-exposures. No extravasation of two kinds of fluorescence dyes, FITC-Dx (MW: 250,000) and sodium-fluorescein (MW: 376), from the pial venule was noticed due to any SARs. Subchronic Exposure Experiment: The values in the diameters and maximal plasma velocity of the pial venule of pre- and post-exposures did not significantly change. No significant differences were recognized between the values for pre- and post-exposures in vascular diameters, plasma velocities and adherent leukocyte counts. No extravasation of the two kinds of fluorescence dyes from the pial venule was noticed (7).

Experimental Procedures 2: In the loop antenna experiment, the head of rat was positioned 2mm under the loop antenna and was locally exposed to 1,439MHz electromagnetic near-field TDMA signal for PDC system. The degree of intensity of EMF exposure was controlled by average specific absorption rate (SAR) of the brain at 0.2, 2.0, and 7.5W/kg for acute effect experiment, and 2 W/kg for subchronic effect experiment, respectively. Other experimental procedures were same with the monopole antenna experiment mentioned above.

Results 2: Acute Effect Experiment: No significant differences were recognized between the values for pre- and post-exposures in maximal plasma velocities and adherent leukocyte counts. No extravasation of two kinds of fluorescent dyes, FITC-Dx and sodium-fluorescein, from the pial venule was noticed due to any SARs. Sub-chronic Effect Experiment: The infection of pia mater, the regeneration of dura mater and the serpiginous change of vessel were not observed within a cranial window of each group throughout the experiment. There was no significant difference in the maximal plasma velocity of the pial venule of each group at 4th week. No extravasation of two kinds of fluorescence dyes, FITC-Dx and sodium-fluorescein, from the pial venule was noticed in any group (7).

Experimental Procedures 3: Rat's head was locally exposed to 1,457MHz electromagnetic near-field TDMA (time division multiple access) signal for PDC (Personal Digital Cellular, Japanese cellular telephone standard) systems by an "8"-shaped loop antenna placed 4 mm upward to the cranial window. RF-EMF exposure intensity was maintained at an averaged SAR (2.0W/kg) in parietal targeted area. During 80 min experimental period including 50 min RF-EMF exposure, three microcirculatory parameters (BBB-function, plasma velocities and vessel diameters) in pial venules were measured every 10 min, and the results were compared between those of RF and Sham groups. Other experimental procedures were same with the monopole antenna experiment mentioned above.

Results 3: No statistical changes were observed between RF group and Sham group in any microcirculatory parameters (26).

Experimental Procedures 4: Possible adverse health effects of radiofrequency electromagnetic field (RFEMF) exposure during mobile phone uses on the developing brain in children are one of the important public health issues. The aim of the present study is to investigate whether RF-EMF exposure induces transient effects on

brain microcirculation being observed only during RF-EMF radiation period in juvenile rats. As juvenile and adult rats, we used 4 and 8 weeks male Sprague-Dawley rats, respectively. Both juvenile and adult rats were divided into two groups: RF group was exposed to RF-EMF and Sham group was not exposed to any RF-EMF. Other experimental procedures were same with the “8”-shaped loop antenna experiment mentioned above.

Results 4: We succeeded to directly observe pial microcirculation through the cranial windows during RF-EMF exposure in juvenile rats. In 4 weeks juvenile rats, no changes in any of the three microcirculatory parameters were elicited by the RF-EMF exposure. No statistical changes were recognized between RF group and Sham group. These negative effects obtained from RF-EMF exposure in juvenile rats were also confirmed in 8 weeks adult rats. No transient effects of RF-EMF exposure on the brain microcirculation in either juvenile or adult rats were recognized (27).

Conclusion: These results from acute and subchronic exposure to RF EMF suggested that no noticeable changes in the cerebral microcirculatory parameters, at least on BBB-function, plasma velocities or vessel diameters, in either juvenile or adult rats under present exposure conditions.

There is an importance of understanding the effects of magnetic fields on microcirculatory system. It may have direct and indirect role in interaction of magnetic fields with different tissues. The results from our studies could be useful in applying them for microcirculatory disorders. In addition, results obtained from exposure to ELF and RF EMFs failed to show any changes in microcirculatory system except for leukocyte and endothelial cell interaction. Levels of EMFs used in our studies are very higher than the international exposure guidelines. These animal studies can contribute to evaluate possible health risks of EMFs.

Abstract

We have pursued the possibility to control immune functions by ELF electro-stimulation. As the first step, the effect of electro-stimulation on the NO producing ability of macrophages was examined. The decrease of NO production due to the electro-stimulation was observed with statistical significance. To elucidate the mechanism of this phenomenon, the amount of the NO synthesizing enzyme was measured. The measurement showed the decrease in the emergence of the enzyme with statistical significance, as well. These facts suggested that the ELF electro-stimulation suppressed the emergence of the NO synthesizing enzyme and that the amount of NO production was consequently decreased by the electro-stimulation. To analyse the association between the amount of the NO synthesizing enzyme and the amount of NO production, the dose-response of this effect was investigated by changing the electric current density of the electro-stimulation. The rates of the decrease in NO synthesizing enzyme and the NO production were found to be very close. These results showed that the change in the NO synthesizing enzyme is closely involved in the mechanism of the suppression of NO production by electro-stimulation. This suggested the feasibility to control the immune function by applying electro-stimulation from outside the body.

Introduction

The influence of ELF electromagnetic field on various physiological functions has been reported, and much study has been conducted mainly from the view point of adverse effects. On the other hand, there is a clinical application such as therapeutic instruments using ELF electric field. With the view towards the immune control by ELF electric field exposure, we have studied the effect of electro-stimulation on cell functions. Macrophages play important roles in a human immune system. We have examined the effect of electro-stimulation on the phagocytic activity and the active oxygen production ability of macrophages. Through this study, it has been found that the both activities are suppressed by the capacitively coupled electro-stimulation^[1,2]. The electric current induced in the suspension of cells was in the similar order to that induced in the human body with the therapeutic instrument of electric field exposure.

In the current study, we have examined the effect of electro-stimulation on the production capacity of nitric oxide (NO). The NO is a kind of the same radicals as the active oxygen and is produced in the immune function of a macrophage. The NO is produced to kill bacteria but can destroy normal cells when produced excessively. Moreover, it reacts with the active oxygen and becomes the peroxynitrite (ONOO⁻). The ONOO⁻ is more toxic and damages normal cells. Therefore, if we can control the NO production, it will contribute to the prevention and the treatment of various diseases. We have examined this possibility by the ELF electro-stimulation in vitro.

Materials and Methods

macrophage preparation

Peritoneal exudate macrophages were used in all the experiments. The thioglycollate medium (4.05%, 2 ml) was injected in the peritoneal cavity of a normal mouse (Std:ddy, female, 7-11weeks). After 3 or 4 days, the cells were harvested from the mouse abdomen. Then, macrophages were collected from the cells in the established method.^[3] We prepared the cell culture solution (RPMI 1640 with L-Glutamine, Sodium Bicarbonate and 10%Fetal Bovine Serum: RPMI 1640, hereafter) with 0.5×10^5 IU penicillin G potassium and 50mg streptomycin sulfate added. The collected macrophages were suspended in the cell culture solution to make the cell density of 2×10^6 cells/ml. When electro-stimulation was applied to the cells, the IFN- γ (10U/ml) and the LPS (1 μ g/ml) were added as stimulants to both the stimulation group and sham group.

electrostimulation system

The macrophage cells were stimulated by the electric current in the container insulated electrically from the electrodes to simulate the condition of electro-stimulation from outside the human body. Figure 1 shows the structure of the sample container.

Two plane electrodes were kept parallel with 3 mm distance by a plexiglass separator. The electrodes were square copper plates (24mm×24mm×6mm top and 32mm×32mm×6mm bottom). The top electrode was insulated with a 0.15 mm thick cover-glass, and the bottom one with 0.10 mm thick silicone film. The outline of the electrostimulation system is shown in Fig.2. Two electrodes were connected to a high-voltage power source through a noise filter. As the power source, the power supply of a commercial apparatus for the electric field therapy was used (Healthtron, Hakuju Inst. Health Science, maximum supply voltage 10kV). A sinusoidal AC signal of 50Hz was supplied to the apparatus with a waveform generator to make the high-voltage with the sinusoidal waveform of 50Hz. In the experiment, the cell suspension was placed in the container, and electro-stimulation was applied in a CO₂ incubator (38°C, CO₂5%). The cell suspension of the sham group was kept in another incubator of the same condition.

Fig.1 Sample container

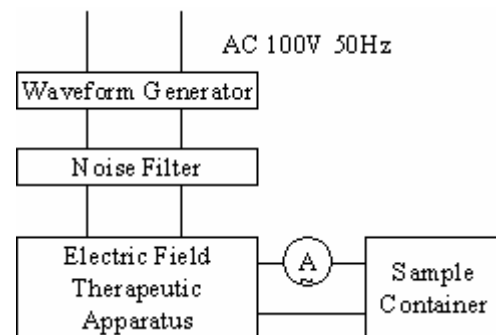

Fig.2 Schematic diagram of electro-stimulation system.

Effect on NO production

We stimulated macrophages in the suspension with IFN- γ and LPS, and applied the electro-stimulation for the exposure group. The sham group was treated in the same way except connecting to the power source. The amount of NO produced outside the cell was measured as fluorescent intensity (495nm excitation and 515nm emission) using fluorescent reagent Diaminofluorescein-2(DAF-2) for the NO detection.

Macrophages were collected in the established method, and washed three times with Hanks' Balanced Salt Solution (HBSS) in centrifugation (400G) for 5 minutes. Then, they were suspended in the culture liquid RPMI 1640 again, and the electro-stimulation (50Hz, 35 μ A/cm², 16h) was applied. After the electro-stimulation, the macrophages were washed with HBSS in centrifugation, and cultured in HBSS suspension with DAF-2(10 μ M) and L-arginine(1mM) two hours without electro-stimulation. After the two hour culturing, the supernatant part was separated in centrifugation. With a fluorescent photometer, the fluorescent spectrum of the supernatant was measured. The supernatant of the sham group was collected in the same process except for the electro-stimulation, and the fluorescent spectrum was measured in the same way as the stimulation group.

Figure 3 shows an example of the measured result. The abscissa is the wavelength and the ordinate is the fluorescent intensity. The wavelength of the intensity peak was around 515 nm in both cases. There was no significant change in the shape of the spectrum, but 30% decrease in the intensity was observed in the stimulation group. This suggests the suppression of NO production by the electro-stimulation. The same experiments were repeated nine times. Figure 4 shows the reduction ratios of the fluorescent intensity between the stimulation and the sham groups. In all the nine cases, the fluorescent intensity was decreased by the electro-stimulation. The p-value of the paired-t test was 1.79×10^{-2} , which suggested the suppression of NO production by the electro-stimulation with a statistical significance.

Fig.3. Example of measured NO production by fluorescence spectroscopy.

Fig.4 Suppression of NO production.

Effect on iNOS expression

NO is synthesized in a macrophage by the inducible nitric oxide synthase (iNOS). To elucidate the mechanism of the suppression in the NO production, the effect of the electro-stimulation on the iNOS expression was examined. The amount of the iNOS expression was evaluated by measuring the fluorescent intensity in the indirect immunity fluorescent method.^[5, 6]

In the same way as the one mentioned above, macrophages were collected, separated into two groups, and electro-stimulation (50Hz, 35 μ A/cm², 16h) was applied to the stimulation group. After the electro-stimulation, the macrophages were collected in the centrifugation. With 70% ethanol, the cell membrane was processed to enhance its permeation. After three times centrifugation (400G, 5 minutes), macrophages were suspended in HBSS. We added the rabbit anti-iNOS antibody (BD Biosciences) and kept it in a shaker bath at 4 °C in 30 minutes. Then we added 20 μ g/ml of the FITC tagged hircine anti-rabbit Ig antibody (MP Biomedicals Inc.) and kept it in the shaker bath. Finally, we fixed the suspension with 1% paraformaldehyde, and measured the fluorescent intensity with a flow cytometer (FACS Calibur Becton Dickinson and Company).

Figure 5 shows an example of the results. The abscissa is the fluorescent intensity in an arbitrary unit, and the ordinate is the number of the cell. The broken line in the figure shows the average intensity of all the cells. The average values were 79 and 65 for the sham (a) and the stimulation (b) cases, respectively. This result showed the decrease in iNOS expression by the electro-stimulation. The same experiments were repeated eleven times. Figure 6 shows the ratio of the average intensity between the stimulation and the sham cases. As shown in the figure, the decrease in fluorescent intensity was observed in all the eleven trials. The p-value of the paired-t test was 5.52×10^{-5} . This suggested that the iNOS expression was suppressed by the electro-stimulation with statistical significance.

Fig.5 Example of measured iNOS expression by fluorescence spectroscopy.

Fig.6 Suppression of iNOS expression.

Analysis of dose-response

As the first step of quantitative evaluation, the dose-response of these phenomena was analysed. In experiments, the amounts of the NO production and the iNOS expression in different current densities ($0.35\mu\text{A}/\text{cm}^2$, $0.675\mu\text{A}/\text{cm}^2$, $3.5\mu\text{A}/\text{cm}^2$) were measured. After the electro-stimulation in 16 hours, the cell suspension was divided into two. One was used for the measurement of the NO production, and another is for that of iNOS expression. Figure 7 shows the results of the measurements. The abscissa is the current density and the ordinate is the fluorescent intensity normalized by that of the sham case. The number of repeated measurements were 4, 6 and 4 for the cases of $0.35\mu\text{A}/\text{cm}^2$, $0.675\mu\text{A}/\text{cm}^2$ and $3.5\mu\text{A}/\text{cm}^2$, respectively. The result of $35\mu\text{A}/\text{cm}^2$ case was added, in which the numbers of the repeated experiments were 11 and 9 for NO and iNOS cases, respectively.

With the current density of $0.35\mu\text{A}/\text{cm}^2$, we could not observe apparent decrease in either of the NO or the iNOS. With $0.675\mu\text{A}/\text{cm}^2$, about 5% decrease was observed. With the current density of more than $3.5\mu\text{A}/\text{cm}^2$, more than 15% decrease was observed. In both of the NO and the iNOS, the threshold of the suppression seems to exist between $0.35\mu\text{A}/\text{cm}^2$ and $3.5\mu\text{A}/\text{cm}^2$. The similar characteristics in the dose-response strongly suggested the close correlation between the suppression of iNOS expression and that of NO production.

Fig.7 Analysis of NO and iNOS suppression effect by electro-stimulation.

Discussion

In the in-vitro experiments, it was found that the NO production is significantly suppressed by the ELF electro-stimulation. This suggested the possibility to control the functions of macrophages by the electro-stimulation applied from outside the body using the apparatus for the electric field therapy. Since a macrophage plays an important role in the first stage of the immune response, the electro-stimulation can influence the entire immune reaction. For example, we can expect the relief from the following diseases. They include the chronic inflammation and the autoimmune diseases caused by an excessive immune response. We can also expect the relief from the endotoxin shock due to the excessive NO production, the etiologic vasodilation, the cardiovascular ischemia, the cerebral hemorrhage and the cancers. Moreover, we have confirmed the suppression of the active oxygen production by the electro-stimulation.^[2] Therefore, we can also expect the control of ONOO^- .

production which shows high cell-toxicity.

However, the finding of this study is only the result of in-vitro experiments using macrophages. We need further investigation to confirm this effect with human macrophages, and the investigation on this effect in-vivo where other kinds of cells are closely interacted. Yoshikawa and his co-workers reported the increase of NO production in the liver when LPS (2 mg/kg) was administered by abdominal injection and the magnetic field (60Hz, 0.1mT) was exposed in 5.5 hours. The current density induced by this magnetic field inside the body is estimated at $1.1 \times 10^{-8} \text{ A/cm}^2$. This result is opposite to our result. It seems that the direct comparison between these two cases is not appropriate, since the object cell and the current density is greatly different among them.

Besides this, there have been few reports on the effect of ELF electromagnetic fields on the NO production, and little has been known on its mechanism. We consider that the arginine metabolism, iNOS activity and iNOS expression are closely associated with the decrease in the NO production. To investigate this mechanism, we have compared the amounts of NO production and the iNOS expression.

Figure 7 shows the coincidence in the reduction ratio of fluorescent intensity between NO and iNOS by the same electro-stimulation. This result suggests that the electro-stimulation affects the NO production through iNOS expression. The signal transmission pathway for the iNOS expression is stimulated by LPS and IFN- γ through receptors on a cell membrane. As the result, a transcription factor is activated and the iNOS is transcribed. In our study, the electro-stimulation was applied from the beginning when we started the stimulation with LPS and IFN- γ . Therefore, it is most plausible that the electro-stimulation affects this process.

However, the following possibility cannot be neglected. In the peritoneal exudate cells used in this study, about 10% cells were not macrophages. Since these non-macrophage cells can affect the signal transmission pathway of the NO production, they might influence the mechanism of the suppression of the NO production. Therefore, we have to examine this point in the experiment using the pure macrophage cells separated from other cells.

In our experiment, the threshold of the effect was found between $0.35 \mu\text{A/cm}$ and $3.5 \mu\text{A/cm}^2$. In the study for the biological effects of ELF electromagnetic fields, the minimum threshold of magnetic field exposure has been reported.^[7] According to the report, the threshold current density for the characteristic change in tissues and cells was in the order of 10 mA/m^2 or $1 \mu\text{A/cm}^2$. Though this threshold is for the electric current induced by magnetic field, it is very close to our result in which the electric current was induced by the electric field.

Conclusion

With the view toward the control of immune functions by ELF electric field exposure, the effect of the electro-stimulation on the NO production of macrophages was examined in vitro. The decrease of NO production due to the electro-stimulation was observed with statistical significance. In experiments, it was found that the expression of NO synthesizing enzyme or iNOS was suppressed in the same rate as NO in the electro-stimulation. Further investigation is required to ascertain this mechanism of NO suppression and to verify the feasibility of the immune control by electro-stimulation.

Abstract

The subject of presented investigations is a spatial distribution of electromagnetic field (EMF) in the workplace, in the vicinity of dielectric heaters where worker's exposure occurs. Detailed spatial distribution of *E*-field in the vicinity of 4 dielectric heaters of various constructions was measured and taken as reference data: 2 dielectric heaters of low emitted field (1 not shielded and 1 shielded) and 2 dielectric heaters of high emitted field (1 not shielded and 1 shielded). Numerical simulations of EMF emitted by numerical model of such devices were carried out with the use of specialized software packages for EMF simulations based on various numerical methods. The comparative analysis of various principles for limitation on workers' exposure to spatially heterogeneous EMF was taken into consideration (EC Directive, IEEE, IEC and EN standards, Polish occupational regulation and standards). The results of measurements and numerical modeling of worker's exposure were discussed, as well as the discussion concerning the worker's protection level corresponding to the use of various spatial averaging protocols while exposure assessment. The obtained results have proved the practical usefulness of various calculations methods for intermediate frequency EMF exposure assessment. The use of the Protection Level Factor, defined by authors for the analysis of the protection level associated with various exposure assessment protocols has been demonstrated at the example of a detailed analysis of electric field from dielectric heaters and its various assessment methods. For example, following the comparison of exposure assessment rules from IEEE standards, EC Directive and Polish regulations - IEEE rules, which seems to be the most liberal for 1 MHz, become to be the most restrictive for the frequency of 27 MHz.

Keywords: EMF exposure, exposure assessment, measurements, numerical calculations, dielectric heaters

1. Introduction

Electromagnetic field's (EMF's) exposure assessment can be required for various purposes, like occupational safety and health (OSH) engineering, epidemiological studies of EMF-exposed groups, environmental monitoring. For all of those purposes, EMF exposure assessment adequate to the real exposure level is the crucial step towards appropriate risk assessment. The highest requirements concerning detailed EMF exposure assessment come from the legislations concerning mandatory control of occupational or environmental EMF exposure. The highest influence on the legislative rules concerning EMF in particular countries come from European Directive 2004/40/EC, ICNIRP's guidelines and IEEE standards. There are also many national regulations implementing various additional rules concerning the protecting of workers against EMF overexposure.

The provisions of the Directive 2004/40/EC are based on the ICNIRP's guidelines in which the limit values of external measures of EMF exposure refer to the electromagnetic fields spatially averaged over the human body. Up to now, it is a lack of European Standards (EN) from CENELEC, harmonized with the Directive 2004/40/EC and focused on details of measurement's procedures and assessment of workers exposure. Various examples of procedures for spatial averaging of electromagnetic fields affecting human body were taken from the existing standards in order to analyze the possible practical consequences of various approaches to solving this problem. Analyzed procedures may be considered as a possible statement for future harmonized standards.

The assessment of the EMF exposure while hand-operating of the dielectric heaters is exactly a practical example of the above-mentioned problems. Dielectric heater's operation involves putting sticking/gluing components from thermoplastic foil between electrodes (upper – powered and lower - grounded) and switching

ASSESSMENT OF SPATIALLY HETEROGENEOUS EMF EXPOSURE

on the RF power (usually of the frequency of 27 MHz). In the case of manual operation, the worker is sitting or standing in front of the device, in the distance of 30 – 50 cm from the electrodes.

During the heating process, the worker is exposed to a spatially heterogeneous field of high electric field strength and relatively weak magnetic component. Usually, it is a sinusoidal time-varying field. These exposure conditions cause that protocol for EMF hazard's assessment should include the real characteristic of exposure and that exposure effects in the worker's body depend on the spatial distribution of the exposure. Such effects are well illustrated by differences in results of calculation of *SAR*, which are shown on figure 1 and in table 1. The calculations were done with a homogeneous model of worker's body, in a sitting position, grounded and exposed to electric fields from the model of dielectric heater or in spatially uniform (homogeneous), vertically polarized field. Both fields are of the same field strength at reference point located in vertical axis of torso of the body model, at height of powered electrode of a dielectric heater. The calculations results of *SAR* values were normalized by the whole body *SAR* (taken as 100%) in worker's body exposed to an uniform field, because such exposure scenario is usually taken for calculations of relation between external (*E* field) and internal (*SAR*) limitations for permissible EMF exposure.

Fig 1. *SAR* distribution in homogeneous grounded model of sitting worker exposed to EMF: a) in front of dielectric heater; b) in vertically polarized uniform field

Table 1.

Results of *SAR* calculations for homogeneous grounded model of sitting worker

	<i>SAR</i> , relative value, %	
	exposure from dielectric heater	exposure in vertically polarized uniform field
<i>SAR</i> - max (10g) local value in the body model	170	1350
<i>SAR</i> - value averaged over whole body	14	100

However, the spatial distribution of *SAR* calculated for both cases is rather comparable with the highest exposure effects localized in ankles, the absolute level of *SAR* values are app. 10-fold higher in the case of uniform field exposure. Various approaches to assessment of spatially heterogeneous EMF exposure in the workplace, where exposure conditions are similar to that in the vicinity of dielectric heaters, were analysed. Exposure limitations and exposure assessment protocols fixed by the EC Directive, EN, IEC, IEEE standards and occupational regulation and standards established in Poland, were taken into consideration.

2. European Directive 2004/40/EC and European Standards

European Directive 2004/40/EC on minimum health and safety requirements regarding the exposure of workers to the risk arising from electromagnetic fields (EMFs) was established in 2004 as the 18th individual Directive within the meaning of Article 16(1) of Framework Directive 89/391/EEC [1]. The EMF's Directive requires that employers undertake risk/exposure assessments using detailed procedures from harmonized European Standards given by the European Committee for Electrotechnical Standardisation (CENELEC), which have not been published yet. This Directive specifies the minimum requirements, thus giving Member States the option of

maintaining or adopting more favorable provisions for the protection of workers, in particular the fixing of lower values for the action values or the exposure limit values for electromagnetic fields. The implementation of this Directive should not serve to justify any regression in relation to the situation which already prevails in each Member State.

The Member States should implement the provisions of the Directive into national legislation by April 2008 and should consider them as minimal requirements against occupational risks due to exposure to EMFs. Detailed comparative analysis of protection levels coming from the Directive's provisions and provisions of existing national regulations and existing national and international standards is very impeded because of the lack of above mentioned European Standards. From the formal point of view, until harmonized European standards from CENELEC cover all relevant assessment, measurement and calculation situations, worker's EMF exposure assessment may be carried out in accordance with other, e.g. national scientifically-based standards and guidelines. Such practice is not guaranteeing that results of exposure assessment carried out according to various protocols will provide comparable conclusions concerning the level of EMF hazard in the workplace.

2.1. EMF exposure limitations established by Directive 2004/40/EC

The employer shall assess and, if necessary, measure and/or calculate the levels of EMFs to which workers are exposed. According to the obligations arising out of the Directive, workers shall not be exposed above the exposure limit values in any event. Additionally, action values were defined for testing and assessing environmental conditions in the workplace. On the basis of the assessment of the levels of EMF, if the action values (external measures as: electric field strength, E , and magnetic field strength, H , in the workplace) are exceeded, the employer shall assess and, if necessary, calculate whether the exposure limit values (internal measures of maximum permissible exposure effects in exposed worker's body as: induced current density, J , and specific energy absorption rate SAR) are exceeded.

The action values are obtained from the exposure limit values according to the rationale presented in ICNIRP's guidelines [3]. External measures are provided strictly as an aid for practical exposure assessments, to determine whether the internal measures are likely to be exceeded. Overexposure concluded from EMF measurements in the workplace do not guarantee that limit values are exceeded in exposed body.

The limit values for electric field strength from the intermediate frequency range are presented within frequency ranges from table 2. The same values were mentioned in the ICNIRP's guidelines, as reference values.

Table 2.

The exposure limitations referring to external measures of the EMF exposure (unperturbed RMS values) - action values from the Directive 2004/40/EC

Frequency range	Electric field strength, E [V/m]
0.82 kHz - 1 MHz	610
1 – 10 MHz	$610/f$
10 – 400 MHz	61

f - frequency in MHz

As these values were calculated for the frequencies above 100 kHz to protect against the thermal effect inside the exposed body, electric field from the workplace should be spatially - and time - averaged for the analysis of the compliance with the internal measures' limitations. Currently, there is a lack of European exposure standards harmonized with above mentioned directive. Protocols from existing product standard concerning the analysis of compliance with ICNIRP's guidelines for general public exposure assessment, obligatory for testing products emitting EMF before entrance to European market (emission product standard), can be considered as a possible source of the protocol for the analysis of compliance with the Directive's provisions.

2.2. Spatial averaging from the EN/IEC product standards

The method of spatially averaging of the results of measurements of EMF is presented in the European standard EN 50357 [2] and IEC Standard 62369-1 [4] for testing the compliance with reference values (external measures published by ICNIRP). Following the provisions of these standards, the torso is the most appropriate part of the body to be assessed and the grid from Figure 2 should be used. The position of the grid in relation to the unit

ASSESSMENT OF SPATIALLY HETEROGENEOUS EMF EXPOSURE

under test can vary according to the typical usage of the EMFs emitting unit, e.g. the height Z should be modified for the assessment of a sitting person exposure. The layout and dimensions of the grid shall remain identical.

For assessment referring to the EMF exposure of torso, the EMF's spatial distribution should be measured in 45 grid points. The result of the arithmetic average of the measured E values should be compared with the limit value from ICNIRP's guidelines. In the exceptional cases where the exposure is predominately to the head, then the grid located in a position referring to the head must be used.

Fig. 2. Torso measurement grid for spatially averaged measurements according to EN 50357 or IEC 62369-1 (normative dimensions: $a, b, c = 15$ cm; $Z = 85$ cm)

3. EMF exposure limitations and assessment by IEEE standards

IEEE Std C95.1-2005[5] provides the recommendations to minimize aversive or painful electro stimulation in the frequency range of 3 kHz to 5 MHz and to protect against adverse heating in the frequency range of 100 kHz to 300 GHz similar to ICNIRP's rationale. The recommendations are expressed in the terms of basic restrictions (BRs) and maximum permissible exposure (MPE) values. The BRs are limits on fields induced in the body, specific absorption rate (SAR), and current density. The MPEs are derived from the BRs. The MPE values for electric field strength from the intermediate frequency range are presented within frequency ranges from table 3.

Table 3.

Electric field maximum permissible values (MPE) from IEEE STd C95.1-2005

Frequency range	Electric field strength, E [V/m]
3 kHz – 1 MHz	1842
1 – 30 MHz	$1842/f$
30 – 100 MHz	61.4

f - frequency in MHz

For spatially heterogeneous exposures, the mean values of the incidental fields should be obtained by spatially averaging the squares of the field strengths. The IEEE Std C95.3-2002 [6] standard provides details concerning exposure assessment protocol for testing compliance with IEEE Std C95.1-2005 provisions.

3.2. Spatial averaging from the IEEE exposure assessment standard

According to IEEE Std C95.3-2002 [6], for the measurement of electric or magnetic fields, carried out for the assessment of the whole-body exposure, spatial averaging of the measurement's results means the root mean square of the field over an area equivalent to the vertical cross section of the adult human body. The spatial average can be measured by scanning (with a suitable measurement probe) a planar area equivalent to the area occupied by a standing adult human (projected area). In the majority of cases, a simple vertical, linear scan of the fields over a 2 m height through the center of the projected area will be sufficient. IEEE document doesn't describe details how to do spatial averaging.

4. Workers EMF exposure limitations and assessment standards in Poland

The occupational safety and health (OSH) legislation in Poland concerns, among others, ambient environmental factors, electromagnetic fields at workplace. Regulations concerning occupational exposure to EMF of 0 Hz - 300 GHz frequency range have been in force since 1972 in Poland as mandatory legislation (current ed. - PL Journal of Laws 217/2002, item 1833 [8]). Regulations are periodically revised and, if necessary, updated under the umbrella of Interdepartmental Commission for Maximum Admissible Concentrations and Intensities for Agents Harmful to Health in the Working Environment, which is the scientific advisory body established by the Prime Minister of the Polish Government.

The main base for all EMF regulations in Poland was taken from the thresholds of thermal and nerve excitation effects, similarly to ICNIRP's approach implemented by the Directive 2004/40/EC. As periodical assessment of EMF exposure level in the workplace is mandatory in Poland, the regulations refer directly to external measures only (E , H). The internal measures (J , SAR) were not directly introduced into published regulations since there is no possibility to measure them in real conditions. However, the permissible internal measures of exposure effects defined by ICNIRP's guidelines (EC Directive) and IEEE Standards were used as an important contribution to theoretical rationale for the level of prohibited exposure to EMF's of various frequencies, drafted as scientific background for above mentioned national legislation.

Following the above-mentioned regulation and Polish Standard, the strength of electric and magnetic fields (E , H), the frequency of these fields (f) and workers' exposure duration (t and exposure factor W), should be taken into consideration for occupational EMF exposure assessment. The main provisions include:

- high exposure - Workers without protective clothes should not have been allowed to access to the area of EMF higher than the level of prohibited exposure (table 4) – the exposure level harmonized with the permissible internal measures from ICNIRP/EC Directive.
- medium exposure - The range of exposure level of permissible EMF exposure duration shorter than 8 hours. In the case that both electric and magnetic fields are relatively high, the exposure factor defining the permissible exposure duration is the sum of components from both fields of the frequency up to 3 GHz. The 8-hours permissible exposure level is the equivalent for ICNIRP/EC Directive external measures' limitation (table 4).

Table 4.

Electric field strength – exposure limitation established in Poland (external measures)

Frequency range	Electric field strength, E [V/m]	
	prohibited exposure	8 hours exposure
$1 \text{ kHz} < f \leq 3 \text{ MHz}$	1000	100
$3 \text{ MHz} < f \leq 15 \text{ MHz}$	$3000/f$	$300/f$
$15 \text{ MHz} < f \leq 150 \text{ MHz}$	200	20

f - frequency in MHz

4.1. Protocol from the Polish Standard PN-T-06580 for workers exposure assessment

Polish Standards determine the protocols how to do EMF measurements and workers exposure assessment (PN-T-06580:2002, revised in 2002 [7]). Worker's exposure assessment should be performed on the results of spot measurements of RMS value of electric and/or magnetic field strength. The maximum value over the worker's body position in the workplace should be considered for testing the compliance of EMF exposure condition with OSH regulations. In practice, it is usually the maximum value of measured electric or magnetic field strength in the vertical axis of worker's body, up to 2 m height.

5. Method

The EMF exposure of workers can be evaluated following the results of calculations in the case when for a particular workplace the exposure assessment on the basis of EMF measurements is not adequate. Such situations occur when EMF's distribution is highly heterogeneous, a worker operates close to the field source or his body is in contact with it. Such exposure assessment needs appropriate modeling of EMF source - for

ASSESSMENT OF SPATIALLY HETEROGENEOUS EMF EXPOSURE

assessment considering external measures and additionally appropriate modeling of workers body - for assessment considering internal measures limitation.

The subject taken for the investigations presented has been a spatial distribution of electric field in the workplace in the vicinity of dielectric heaters where worker's exposure occur.

A detailed spatial distribution of E -field in the vicinity of 4 dielectric heaters of various construction was executed: 2 dielectric heaters of low level of emitted field - 1 not shielded (M-m1) and 1 shielded (M-m2); 2 dielectric heaters of high level of emitted field - 1 not shielded (M-d1) and 1 shielded (M-d2). Measurements were done by RMS value meter with isotropic probe. Three dimensional components (X, Y and Z) of electric field strength have been recorded online using notebook computer. The recording system is shown on figure 3. A measuring probe was placed in succeeding appointed points along measuring lines. The registration of only one single pulse was done at each measurement point.

Fig. 3. Online registration system used for EMF measurement for data – acquisition in the vicinity of real dielectric heater.

Numerical simulations were carried out with the use of specialized software packages for EMF simulations based on various numerical methods:

- OPERA 3D v. 8.7 (Vector Fields Ltd, United Kingdom) – specialized for finite element method – FEM
- CST MICROWAVE and EM STUDIO (CST – Computer Simulation Technology - Germany) - specialized for finite integration technique – FIT.

The geometrical model of dielectric heater is shown in figure 4. EMF's source for this numerical modeling was created by powered electrode of 1 kV electrical potential.

Fig. 4. Geometrical model of dielectric heater.

6. Results

Spatial distribution of E field in the vicinity of dielectric heater obtained from calculations and measurements have been averaged over the volume of worker's torso (following EN/IEC standards' protocol) and over the vertical axis of workers body position (following IEEE standard protocol). Averaging of measurements results have been carried out on the base of maximum values registered from each welding pulses. The results were presented in fig. 5 as values relative to the maximum value over the workers body which is taken for exposure assessment following the protocol established by Polish Standard PN-T-06580. Bars representing various measurements result's averaging are labeled in figure 5 as M-m1; M-m2; M-d1 and M-d2 (with above mentioned meaning). Bars representing averaging of calculation's results are labeled as follow: C-s1 - from Opera software, C-s2 - from CST MW and C-s3 - CST EM.

Fig. 5. Spatial averaging over the workplace the E -field from dielectric heaters

The data concerning E -field spatial distribution, obtained from simulations with the use of very simple model of EMF source and various software, averaged over the workers body presented the similar relation to maximum value of E field at workplace (0.43-0.51) as the ratio observed among the measurement results from real workplace (0.35-0.85). Thanks to this fact, obtained results of calculations suggest that various numerical simulations' methods could be acceptable for calculations executing for the assessment of intermediate frequency EMF occupational exposure. Very simple models of EMF source can be also accepted, but "calibration" of the calculation results has to be done by the comparison with measurement results to obtained confirmation concerning the absolute values of exposure level (E -field).

For a deeper analysis of the practical consequences of the use of various exposure assessment protocols and limit values, the protection level coefficient can be consider. Protection Level Factor (PLF) can be define as the ratio of the exposure estimator taken for exposure assessment on the basis of particular exposure assessment protocols (e.g. various spatial averaging protocols above mentioned), divided by exposure limitation harmonized with this protocol (e.g. E field averaged following the protocol from IEEE C95.3 divided by limit value fixed by IEEE C95.1). With such definition, PLF of higher value correspond to the more restrictive exposure assessment rules, or in other word, higher protection level.

The practical usefulness of the analysis of various exposure assessment rules with the use of PLF value can be show at the example of electric fields of spatial distribution like in the vicinity of dielectric heaters and maximum value at the axis of worker's torso of 1000 V/m, assessed following the limit values from tables 2-4. The field taken for the analysis can be described by max value of 1000 V/m, value averaged following IEEE rules of 700 V/m and value averaged following EN/IEC rules of 500 V/m. For such values, in the case of electric field of frequency of 1 MHz, PLF values are: for the exposure assessment rules established by the European Directive and EN/IEC standards – $PLF(IEC, 1MHz) = 0.8$; for exposure assessment rules established by IEEE standards – $PLF(IEEE, 1MHz) = 0.4$ and for exposure assessment rules established in Poland as the threshold of prohibited exposure – $PLF(PL, 1MHz) = 1$. In the case of electric field of 27 MHz PLF values have different order: $PLF(IEC, 27MHz) = 8$; $PLF(IEEE, 27MHz) = 10$; $PLF(PL, 27MHz) = 5$ – IEEE rules, which seems to be the most liberal for 1 MHz, become to be the most restrictive for the frequency of 27 MHz.

7. Conclusion

These investigations can support the work on methods of numerical simulations for the routine assessment of worker's exposure to EMF from intermediate frequency range. There is relatively a wide gap of experience of "numerical" assessment of worker's exposure to EMF from intermediate frequency range in comparison with the huge amount of data concerning power frequency and microwave.

The selection of geometry of EMF source's models, as well as the selection of numerical simulations methods can significantly influence on the level of obtained results, however the relative spatial distribution of E-field could be similar.

Presented methodology of analysis of the protection level which is associated with various exposure assessment protocols can be use for detailed comparative analysis of various exposure limitation standards, legislation or guidelines. The overall analysis should consider not only the spatial averaging of incidental fields but also rules of time-averaging of non-continuous exposure, calibration of measurement devices for non-sinusoidal fields, etc. components of exposure assessment protocols.

ABSTRACT

The present work deals with the active suppression of an electromagnetic field (EMF) of complicated multi-circuit transmission lines and its practical realization. This research is the continuation of a previous one [1], in which more simple case of only one (single) transmission line EMF was investigated and a method of its suppression proposed.

In double circuit transmission systems, for instance, the EMF has an elliptic space-time characteristic, as the big and small axes of the ellipse can be approximately of the same lengths.

The active suppression of an EMF in such cases can be carried out by means of two loops installed in parallel to the transmission lines having independent automatic control of the currents in each loop.

The method of calculating the EMF of the transmission system and of the loops and the computer program for performing such calculations, have been developed in this work. Based on these calculations, loop parameters and their arrangement in space may be determined.

As a result of the research, a practical application (pilot installation- see the pictures) of the suppression of EMF, induced by a high voltage (160kV) double transmission line in an office building of an industrial zone of the city of Rosh Haayin has been performed. Two loops located along the protected office have been installed and activated by a control system. The experimental results of such protection were in very good agreement with the theoretical predictions. The electromagnetic field in various points of the protected office has been reduced 3-10 times, so that the suppressed EMF became less than the permissible value.

INTRODUCTION

In the previous research [1] it was shown that the space-time characteristic of the EMF of a single transmission line has very narrow elliptic form. It was also shown that the suppression of such EMF could be done by using a single loop, whose space-time characteristic is a straight line. The suppression is achieved when the parameters of the loop (its ampere-turns and position in the space) are chosen in such a way that its straight-line-characteristic coincides with the big axis of the elliptic-characteristic of the transmission line EMF and equals it in length. The two EMF's of the line and the loop of course have to be of opposite phases.

ELECTROMAGNETIC FIELD GENERATED BY A COMPLICATED POWER LINE

Let us now analyze a double-circuit transmission line having any phase sequence. Fig. 1 shows such a line going in parallel to a four story building.

Fig.1 Three-phase double-circuit power line and a protected building

Let $P(y, z)$ be the point, where we wish to calculate the magnetic field (the point of observation), where y, z are the coordinates of the point of observation. (In this case the observation point is located on the third floor).

In accordance to the Biot-Savart law the magnetic flux density produced by an infinite conductor is:

$$B(y, z, t) = \frac{\mu_0}{2\pi} \frac{I_m \sin(\omega t - \alpha)}{R(y, z)} \quad (1)$$

where μ_0 is the magnetic permeability of air, $I_m \sin(\omega t - \alpha)$ is the current carried by the conductor and

$R_i(y, z)$ is the distance from i -phase to the point of observation.

$$R_i(y, z) = \sqrt{(y_i(y))^2 + (z_i(z))^2}, \quad (2)$$

where $y_i = y - Y_i$, $z_i(z) = z - Z_i$ and Y_i and Z_i are coordinates of an i -phase.

Then the vertical and horizontal components of EMF are defined by the expressions:

$$\begin{aligned} BV_i(y, z, t) &= B_i(y, z, t) \frac{y_i(y)}{R_i(y, z)} \\ BH_i(y, z, t) &= B_i(y, z, t) \frac{z_i(z)}{R_i(y, z)} \end{aligned} \quad (3)$$

The sum of the vertical and horizontal components at point $P(y, z)$ for a three-phase double-circuit line is

$$BV(y, z, t) = \sum_{i=1}^6 BH_i(y, z, t) \quad (4)$$

given by:

$$BH(y, z, t) = \sum_{i=1}^6 BH_i(y, z, t)$$

With the vertical and horizontal components (4) the space-time characteristic of the transmission lines EMF is built and shown in Fig.2. As can be seen, the obtained ellipse is pretty wide so that the successful suppression of EMF by use of only one loop cannot be achieved.

Fig. 2 An elliptic characteristic of EMF

In Fig.3 the above two components (4) are shown as functions of the distance from the office wall, parallel to the transmission lines, along the y -axes, and in Fig. 4 they are shown along the z -axis from the floor up to the ceiling. The origin of these coordinates is located at the point of the location of the sensor, which activates the control system).

Fig. 3 Effective values of transmission lines' EMF inside the office: 1-horisional, 2-vertical components

Fig. 4 Effective values of transmission lines' EMF in the office versus height: 1-horisional, 2-vertical components

ACTIVE SUPPRESSION OF EMF: PRACTICAL REALIZATION

Both components of the EMF, of course, can be measured and compared with the one computed and, if the line currents and the phase sequences are presented by their actual values, the computed values (Figs 3 and 4) should be in agreement with the measured ones. Now, being sure that the picture of the EMF is correct we can design the compensation loops.

ELECTROMAGNETIC FIELD GENERATED BY COMPENSATING LOOPS

Since the EMF of a two-circuit transmission system is expressed by the wide ellipse, as is mentioned above, the suppression of such a field should be performed by means of two perpendicular loops, as shown in Fig. 5. In this case the protected area is the office of ECTEL Company. (The position of the sensor, which activates the automatic control system, is indicated by ©)

Fig. 5 The position of the protecting loops

The EMF of these loops is calculated as a sum of the vertical and horizontal components of all four lines:

$$BV_l(y, z, t) = \sum_{i=1}^4 BV_{li}(y, z, t) \quad (5)$$

$$BH_l(y, z, t) = \sum_{i=1}^4 BH_{li}(y, z, t)$$

The suppressed field ($BVs(y, z, t)$, $BHs(y, z, t)$) is then obtained as a sum of the vertical and horizontal components of the transmission line system ($BV(y, z, t)$, $BH(y, z, t)$) and the loop system ($BVl(y, z, t)$, $BHl(y, z, t)$):

$$BV_s(y, z, t) = BV(y, z, t) + BVl(y, z, t)$$

$$BH_s(y, z, t) = BH(y, z, t) + BHl(y, z, t) \quad (6)$$

As it was already mentioned, the vertical loop (loop 1) should be positioned in such a way that its characteristic (line 2 in Fig. 6a) will coincide with the big axes of the ellipse (line 1 in Fig. 6a). The resulting EMF is also shown in Fig. 6a as line 3, which actually is an ellipse, but due to the relatively small scale looks as a line. Then the horizontal loop (loop 2) is designed and positioned in such a way that its characteristic (line 2 in Fig. 6b) coincides with the small axis of the original ellipse (line 1 in Fig. 6a). Note that this small axes after the first compensation turns into the big one, as shown in Fig. 6b (1). (Also note that line 3 in Fig. 6a now looks like an ellipse in Fig. 6b due to the larger scale). After the second compensation (by loop 2) the resulting EMF is suppressed up to the very small ellipse (3), which again looks like a straight line.

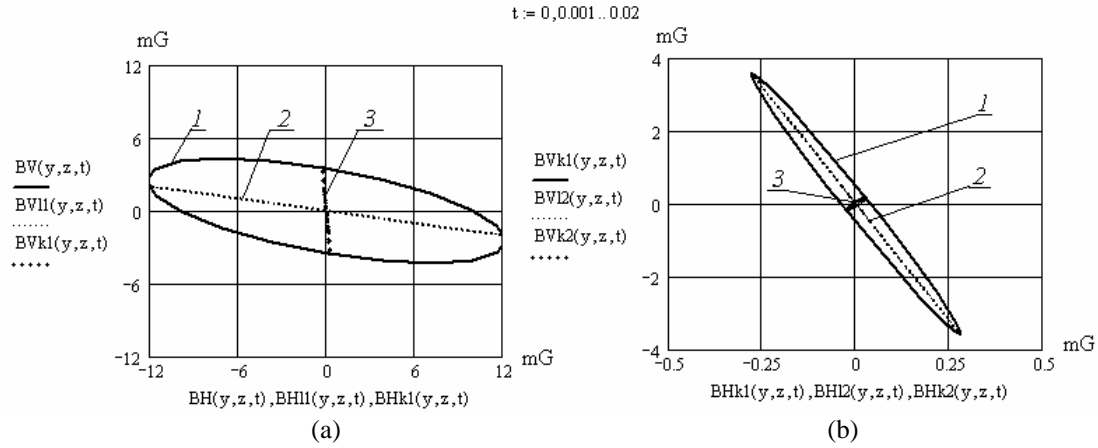

Fig. 6 The field characteristics of the transmission lines (1) and the loops (2 and 3)

The resulting curves of the suppressed field (curves 1) and the curves of the original field (curves 2) are shown in Fig. 7a and b. It should be mentioned that the minimum point of the suppressed EMF is at the position of the sensor. Therefore, by choosing this position we can influence the distribution of the suppressed field along the office/home.

Fig. 7 The EMF distribution inside the office: versus the distance from the wall (a) and the height (b) (1-original field, 2-suppressed field)

PRACTICAL REALIZATION

For checking and proving the proposed method of EMF suppression an experimental sample of a suppressing system to protect an office (of ECTEL Company in Rosh Haain) was projected and installed. The front of the office building and the loop installation is shown in Fig. 8. The same installation as seen from the corner of the building and the transmission line are shown in Fig. 9.

The resulting curves of the suppressed EMF along the protected office along with the original EMF (before the compensation) are shown in Fig. 10a and b: the calculated curves (a) and measured (b). As can be seen, there is a good agreement between the theoretical and practical results. The remaining EMF inside the office does not exceed 2.5mG, which is the required norm [3].

ACTIVE SUPPRESSION OF EMF: PRACTICAL REALIZATION

Fig. 8 The picture of the protecting loops in the front of the building

Fig. 9 The picture of the protecting loops and the transmission lines from the corner of the building

Fig. 10 The resulting curves of the EMF: calculated (a) and measured (b) (1-original field, 2-suppressed field)

SUMMARY

The method of active suppression of the EMF induced by a complicated system of high voltage, large power transmission lines is developed and practically performed.

It is shown that in such cases the protecting system comprises two compensating loops, which should be arranged in space perpendicularly to each other, usually one lies in the vertical plane and the second one in the horizontal plane.

The pilot installation, based on the proposed method, was performed and tested on one of the offices in the building, located near to a high voltage transmission system.

The pilot performances are very successful: the original EMF has been suppressed 3-7 times, so that the remaining EMF is of 2-2.5mG, which is required the norm.

Abstract

The quick growth of mobile communication has led to investigate the possible adverse effects on public health. In spite of security regulation norm for public exposure by governments from different countries all around the world, the current controversy lies now on the possibility that the ELF could produce biological non-thermal effects. Nowadays some scientists are concerned about the possible impact of ELF fields of mobile phone. Magnetic ELF component are mainly generated by supply current in the phone.

In order to achieve a practical conclusion about sensitivity of nervous system to cell phone, the magnetic flux density in 217Hz and its harmonics from cell phone battery current were measured and these data will be used for stable magnetic field coil that made electrically for studying the effects of environmental ELF fields on bioelectric activity of nerve cell.

For measuring ELF fields of cell phone resulted from battery current, an on-made search coil was provided and calibrated precisely under several experimental conditions. Using Fast Fourier Transform (TSM-DSO Software) the power spectrum of induced voltage in search coil was analyzed and the amplitudes of 217Hz and its harmonics were extracted, considering the difference between induced voltage in search coil and magnetic

flux density of cell phone in 217Hz component and its harmonics, we measured a range of power variation in different times of the day.

The results of this study suggest that, ELF B-field of cell phone was not the same in different points. These findings emphasize the need for caution and regard all variations of power range during the different time of the day when biological effect of magnetic fields from cell phone is studied. To reach windowing effect, we must consider the physical characteristics of fundamental component wave (217Hz) and its harmonics produced by mobile phone accurately near to real one in exposure system.

Keywords: Mobile phone, ELF magnetic fields, 217Hz

Introduction

Modern technology offers powerful tools to stimulate a range of benefits for society, in addition to economic development. However, technological progress in the broadest sense has always been associated with hazards and risks [1].

Radio frequency transmitted by digital GSM telephones in the 900MHz band (890-915MHz) belongs to the "heating" category of the frequency spectrum. Hand-held digital mobile phones generate pulsed magnetic fields resulted from battery current, they transmit information in burst of microwaves and operate in one of the eight time slots, i.e. sending the information to the base station in 0.577 ms bursts with 217 bursts per second. This pulsed magnetic field (MF) of extremely low frequency (ELF) mainly include 217Hz (pulse their harmonics and subharmonics) [2]. It is quite possible that living organism have two- fold sensitivity to the pulsed GSM signal, to both the microwave carrier and lower frequency pulsing "time division multiple access"(TDMA)[3]. Besides a large number of researches which have been focused on high frequency components much less attention has been paid on the low frequency pulsed magnetic fields associated with pulsed battery current characteristic for GSM-type mobile phone [4,5,6,7,8,9,10,11].

The pulsed ELF-MF in mobile phone signals could exert influence on biological systems through non-thermal effects and this ELF emission is itself capable of causing significant biological effects [4]. In contrast to heating, which relies on an organism's ability to absorb energy from irradiating field, the possibility of non-thermal effects arises from an "oscillatory similitude" between the radiation and living organism to respond to low-intensity pulsed via its ability to recognize certain frequency characteristics of that radiation, in fact non-thermal effects are non-linear [3].

The existence of specific amplitude and frequency values at which the response of the object was more pronounced. The sensitivity of the biological systems to weak MF has been described elsewhere, mainly in respect to the dependence of bioeffects on the amplitude or the frequency of the applied fields. More and more studies have suggested that for non-ionizing radiation cannot be applied the principle of ionizing radiation when the increase of the dose enhance the effects [12].

Thus in this paper we monitored the environment intensities of magnetic field emitted by one model of digital cell phone to settle the experimental conditions in order to reproduce the pattern of waves of mobile phones in a configuration closer to real condition.

These ranges of intensities will be used for studying the effects of environmental ELF battery's fields on bioelectrical activities of nerve cell.

Material and Methods

The assessment ELF fields of GSM mobile phones requires a search coil, according to Faraday's induction law the variable magnetic field induces a voltage in wire winding. The average diameter of on-made search coil was 5mm with 500 turns wire with 0-260kHz frequency response. For RF immunity the probe was shielded with aluminum foil.

To obtain calibration factor, the search coil was exposed with known magnetic field. It was done with a system when an accurately known current with 217Hz frequency was injected through the circular coil (drived by known signal). The flux density of magnetic field was measured by a hand-held digital magnetic field meter (TES 1394, Electronic Electrical Corp.).

The calibration factor ($\mu\text{T/mV}$) was the ratio between flux density (B) and induced voltage in search coil that measured with the analog oscilloscope (Topward 7046A).

For scanning the surface B-field (flux density) distribution on the back side of the mobile phone a 10×10mm grid (Figure 1), in a way that the search coil was situated 4mm far from battery surface, was used. With considering the surface of battery we had 15 points on the back side of phone and we measured induced voltage in three axes in different times of the day in each points. The amplified induced voltage (root mean square) in search coil was measured with digital oscilloscope (DSO, TNM Electronics). By using Fast Fourier Transform (FFT) method (TNM-DSO software), the power spectrum of induced voltage was analyzed and the power of 217Hz component and its harmonics were extracted and saved in computer. Then, the B-field in 217Hz calculated with calibration factor.

Figure 1- 10×10mm grid for scanning B-field of mobile phone

Results

Ten experiments were carried to calculate calibration factor. The magnetic flux densities in 6 cm far from the circular coil were measured with digital magnetic field meter and induced voltage in search coil measured with the analog oscilloscope. According to the ratio B/V , where B is the B-field of circular coil and V is the induced voltage in the search coil, we calculated the calibration factor (Figure 2). The calibration factor was $51.57 \mu\text{T/mV}$ with .997 regression coefficient.

Figure 2- Measured magnetic flux density (B) and induced voltage (V) at 6 cm far from the circular coil

The induced voltages (rms) in 217Hz component of the sum vector of all three axes ($B_s = \sqrt{B_x^2 + B_y^2 + B_z^2}$) in different times of day in 15 points on the back side of phone were measured (Table 1). The measured induced voltage waveform is shown in Figure 2. It consists of pulses train. The duration of pulse is 0.577ms and the repetition interval is 4.61ms that are the same of sending information to the base station with 217 Hz (Figure 3).

Table 1-The sum vector of three axes of induced voltage in 217Hz in different times of day

Induced Voltage (rms in mV)	Maximum	Minimum	Average
Morning	2.77	0.25	1.39
Afternoon	1.62	0.19	0.80
Evening	2.09	0.23	0.81

Figure 3: Induced voltage waveform in 217 Hz

The power spectrum of induced voltage was analyzed by Fast Fourier Transform (FFT) method and the amplitude of induced voltage in 217Hz and its harmonics were extracted (Table 2)(Figure 4).

Table 2- The sum vector of three axes of induced voltage in 433Hz and 650 Hz in different times of day

Induced Voltage (rms in mV)		Maximum	Minimum	Average
433Hz	Morning	2.57	0.24	1.31
	Afternoon	1.54	0.13	0.74
	Evening	1.99	0.22	0.77
650Hz	Morning	2.24	0.19	1.10
	Afternoon	1.21	0.07	0.61
	Evening	1.68	0.18	0.64

B-field distribution on back side of mobile phone is the result of the surface scan with 4mm distance between the phone's surface and search coil. The distribution pictures show the 217 Hz component of sum vector of all three axes of induce voltage(rms) times calibration factor (MATLAB software, version6.5, the Math Works Inc.)

Figure 4- The power spectrum of induced voltage in 217 Hz and its harmonics

Figure 5- B-field distribution on back side of mobile phone

Discussion and Conclusion

The obtained results clearly show that the amplitude of induced voltage (rms) in 217 Hz and its harmonics considerably varies in different points of handset's battery back side. In this study, the results of changing magnetic fields from battery phone are not new and our research outputs were similar to the other works [5].

In addition to the other works we measured the B-fields in different parts of the day (Morning, Afternoon and Evening) according to network jam. So, we obtained a power range of induced voltage from 0.07 to 2.77 mV and B-fields between $26.40\mu\text{T}$ to $86.52\mu\text{T}$. We had done our experiments in Iran workplace.

Furthermore the relative powers of two main harmonics to fundamental component were 94% and 78%.

As it may be interesting to know that all early publication made a link between "windows" and information transfer it is better to consider a range of intensities. So, for reasonable approach to the ELF "windows" problem we must consider a range of parameters such as magnetic flux density (amplitude) or frequency. In this way it appears reasonable to claim the existence of "window effect".

Besides considering the range of intensities, it should be stressed that for biological studying of mobile phone, according to the power spectrum analysis, we must consider the intensities of higher harmonics of fundamental component, in addition to 217Hz signals, in ELF exposure systems.

To properly assess the validity of any experimental results demonstrating cell phone bioeffects, it is necessary to understand the mechanism by which these effects may occur.

Further investigation is on the way to settle the experimental condition in order to reproduce the pattern of the waves of mobile phones in a configuration closer to real one and examining the effects of low-frequency component of mobile phone on nervous system.

Abstract

RF power control is used to minimize the transmit power required by the mobile or base station subsystem while still maintaining the quality of the radio links. By minimizing the transmit power levels, interference among co-channel users can be reduced.

For circuit-switched services in GSM system, the mobile is commanded by the base station to change its power level. The base station directs this process with the help of the uplink receiving level and quality measurements.

In this paper we consider dependence between maximum output power level of GSM mobile phone and receiving level.

The measurements were performed with GSM mobile phones, which used service software in the networks of the three PLMNs (Public Land Mobile Network) in Bulgaria.

Our results indicate the receiving levels in those the GSM mobile phone transmit with maximum output power.

Introduction

The adaptive power control allows the mobile station (MS) to increase or decrease output power level for provides of reliable communications. It also decreases interference with other co-channels users and, through dense frequency reuse, improves spectral efficiency, while maintaining an adequate communications quality and facilitates a reduction in power consumption, which is particularly important in hand-held MSs. And not the lastly place decrease of the output power level provides to decrease of absorbing energy (decrease of Specific Absorption Rate SAR) in the head of a user, which is particularly important for the users of mobile phones.

The power control procedure is accomplished by during a call (when the MS is in Traffic CHannel – TCH) and it controls from base station (BS). Output power level of MS for GSM900 can be reduced in 15th steps from 33dBm (2W) to 5dBm (3.2mW) and each step is 2dBm [1].

The adaptive power control procedures rely on measurements of the received RF signal strength (RXLEV), the received signal quality (RXQUAL) [2].

RXLEV is evaluated by measuring the received level of the broadcast control channel (BCCH) carrier, which is continuously transmitted by the BS on all time slots of the B frame in Fig. 1 and without variations of the RF level. An MS measures the received signal level from the serving cell and from the BSs in all adjacent cells by tuning and listening to their BCCH carriers. The root mean squared level of the received signal is measured over a dynamic range of -103dBm to -41dBm for intervals of one slow associated control channel (SACCH) multiframe (480 ms). The RXLEV parameters are then coded into 6-bit words for transmission to the serving BS via the SACCH.

RXQUAL is estimated by measuring the bit error rate (BER) before channel decoding, using the Viterbi channel equalizer's metrics and/or those of Viterbi convolutional decoder [3]. Eight values of RXQUAL span the logarithmically scaled BER range of 0.2% to 12.8% before channel decoding.

THE DEPENDENCE BETWEEN MAXIMUM LEVEL OF OUTPUT POWER MOBILE PHONE AND RECEIVING LEVEL

system during an originated call are occupy as following [7]:

BCCH/CCCH	Broadcast Control CHannel/ Common Control CHannel	

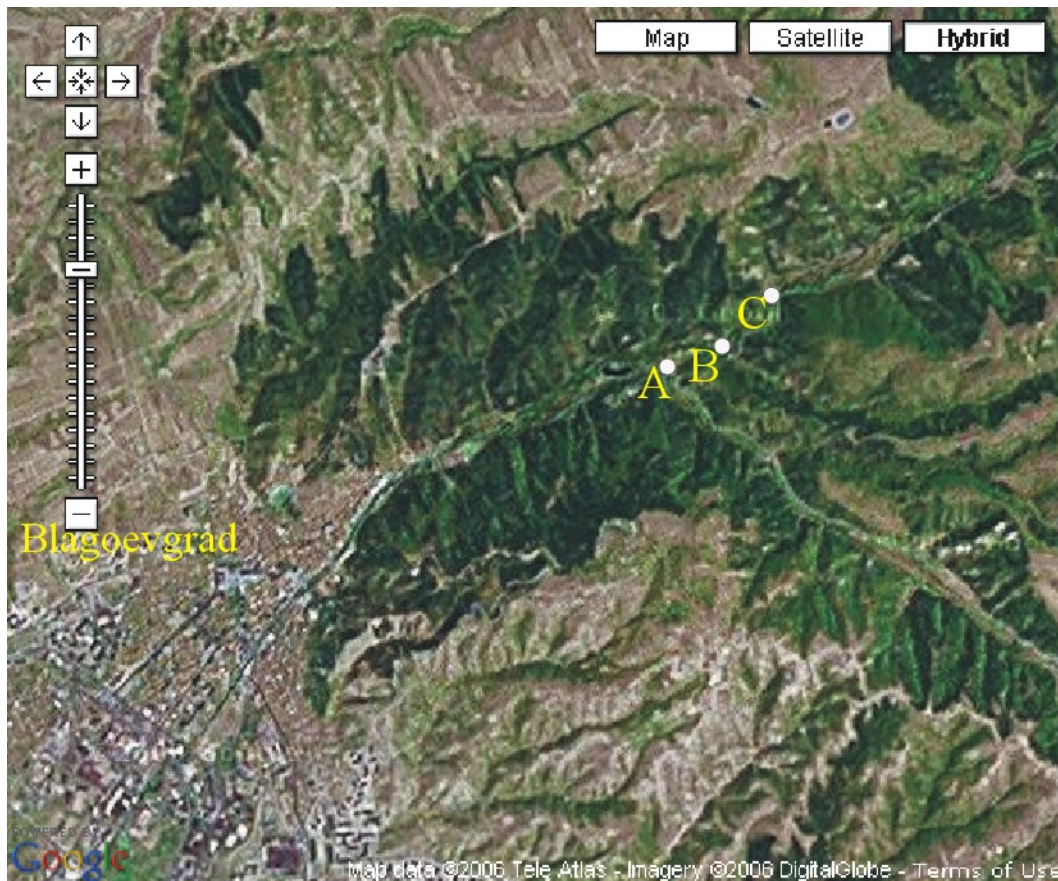

Figure 2. Placement of the points of measurements in outskirts with hilly relief and trees.

Figure 3. Placement of the first point of measurements in urban area.

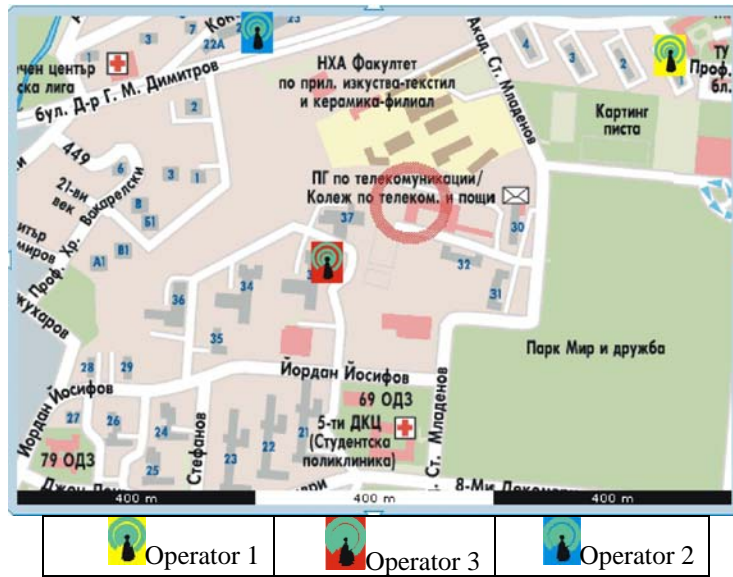

Figure 4. Placement of the second point of measurements in urban area.

Results

The results of the measurements are displayed of Figs. 5...19.

“Pointing” assessments for showing of the uncertainty of the measurement were determinate [8]. “Directed” assessment of statistical moments of the investigated accidental value and more specific – of the mathematical expectation \hat{m}_x and dispersion $\hat{\sigma}_x^2$ [9] were performed.

The point assessments of performed n (where $n=10$) independent measurements with registration implementations $x_1, x_2, \dots, x_i, \dots, x_n$ of the accidental value X is as following:

$$\hat{m}_x = \frac{1}{n} \sum_{i=1}^n x_i, \hat{\sigma}_x^2 = \frac{n}{n-1} \left[\frac{1}{n} \sum_{i=1}^n (x_i)^2 - \hat{m}_x^2 \right] \quad (1)$$

The root mean squared deviation $\hat{\sigma}_x$ was evaluated.

The “interval” assessments for specific cases displayed of Figs. 8(a, b), 9(a, b), and 10(a, b) were determinate on the base of the “pointing” assessments of \hat{m}_x and $\hat{\sigma}_x$ by (1).

THE DEPENDENCE BETWEEN MAXIMUM LEVEL OF OUTPUT POWER MOBILE PHONE AND RECEIVING LEVEL

The half-magnitude of the confidential interval $\varepsilon = \frac{I_{m_x}}{2}$ and confidential boundaries were determinate, as following:

$$m_1 = \hat{m}_x - \frac{\hat{\sigma}_x}{\sqrt{n}} A', \quad m_2 = \hat{m}_x + \frac{\hat{\sigma}_x}{\sqrt{n}} A', \quad (2)$$

where $A' = 1.960$ with $p_I = 0,95$.

m_2	-81.345	33.000
ε	0.128	0.000

The received data in course of the present investigation (Figs. 5...10; Tables 1...6) showed that received level RXLEV in that output power level TXLEV of the mobile station is 33dBm for:

- Network operator 1 is approximate: -81dBm;
- Network operator 2 is approximate: -85dBm;
- Network operator 3 is approximate: -81dBm.

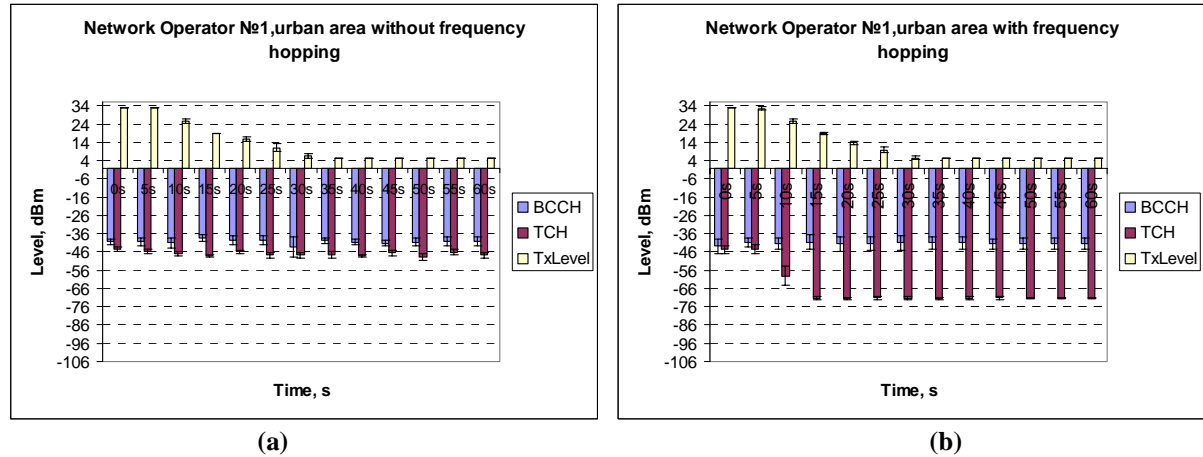

Figure 11. Presentation of average data of RXLEV, RXLEV_TCH, and TXLEV for Network Operator 1 in points indicated in Fig. 3: (a) without frequency hopping; (b) with frequency hopping.

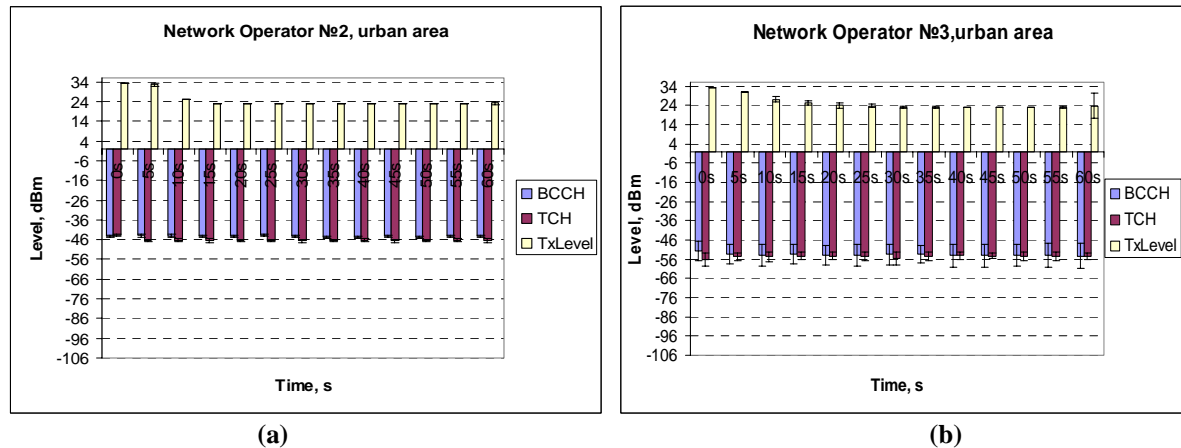

Figure 12. Presentation of average data of RXLEV, RXLEV_TCH, and TXLEV in points indicated in Fig. 3: (a) for network operator 2; (b) for network operator 3.

Analysis of the data from Figs. 11 and 12 showed that in the urban area output power level of the MS decrease during a call. The boundaries of the lowest output power levels of the MS are different, from 5dBm for network operator 1 to 23dBm for network operators 2 and 3. Based on these results can be seen, that values of the received levels of BCCH carrier for network operators are between -54dBm ... -40dBm. Therefore, BSs of the operators are equally distant from the point of measurement. In the same time the alterations of output power level of the MS are different for the network operators. The different strategies for RF power control of the network operators are confirm from these results.

Adaptive power control of MS for the network operators starts after initial 10 seconds (see Figs. 8(a), 9(a), 10(a), 11, and 12). The reason for this is that during these seconds MS occupied controls channels; it is confirmed form the results illustrated of Fig. 13.

THE DEPENDENCE BETWEEN MAXIMUM LEVEL OF OUTPUT POWER MOBILE PHONE AND RECEIVING LEVEL

Figure 13. Presentation of average data of TXLEV in points indicated in Fig. 4.

In Fig. 11(a) TCH and BCCH channels using the same carrier, and have similar levels.

In Fig. 11(b) the TCH carrier is different from the BCCH carrier. In this case received level of TCH carrier is lower than level of BCCH carrier, it's mean that transmission power of BS is lower compared with the case from Fig. 11(a).

Summary

On the basis of the results of measurements of RXLEV, RXLEV_TCH, TXLEV, RXQUAL, and DISTANCE in the three points from Fig. 2 were established average value on the received levels RXLEVs in those output power level TXLEV of the mobile station is 33dBm (2W). Therefore, the received values (RXLEV \approx - 85dBm ...-81dBm) can be used to provide a reference levels.

These results can be applied to found the areas (points) in those output power level TXLEV of the mobile station is 33dBm (2W).

The results from the investigation demonstrated that adaptive power control of MS depended on level of BCCH carrier, but not of the level of TCH carrier (see Figs. 11(a, b)).

The results received via measurements in real operating conditions can be useful for further *in Vitro* and *in Vivo* investigations for the influence of the GSM mobile phones on the man.

Finally, according to reference from [10] to necessary to determine a complex of hygienic requirements to a mobile telephone, allowing the subscriber to realize the right of a voluntary choice of a comprehensible risk level and according by the World Health Organization recommendations to subscriber can be suggest: 1. During the first 10 seconds the mobile phone transmitted with maximum power 2 Watts, therefore, in this time the mobile phone must be distant from subscriber's head; 2. When the bars displaying receiving level strength of the mobile phone display are smaller from the maximum number, then the mobile phone will be transmit with maximum power during a call.

STRESS HORMONE REACTIVITY IN MEDICAL STAFF EXPOSED TO ELECTROMAGNETIC RADIATION

MICHEL ISRAEL, KATIA VANGELOVA,
DESIMIRA VELKOVA, MICHAELA IVANOVA

NATIONAL CENTER OF PUBLIC HEALTH PROTECTION,
15 ACAD. IVAN GESHOV BLVD., 1431 SOFIA, BULGARIA

Abstract

The **aim** of the investigation was to study the effect of electromagnetic radiation (EMR) on stress hormone reactivity of medical staff in physiotherapies. The excretion rates of stress hormones cortisol, adrenaline and noradrenaline were followed during morning shift in 15 female physiotherapists using RIA kits and a spectrofluorimetric method. The mean number of treatments with EMR emitting devices per month and the emission of each device was followed. A control group of nurses, matched by age, sex and work task was followed. The psychosocial factors were followed and showed no differences between the two groups. Significantly higher excretion rates of cortisol ($F_{(1,69)} = 7.171$, $p = 0.009$), adrenaline ($F_{(1,69)} = 7.869$, $p = 0.007$) and noradrenaline ($F_{(1,69)} = 10.643$, $p = 0.002$) with the studied physiotherapists in comparison with the control group of nurses was found. In conclusion, our data showed that EMR influenced stress hormone reactivity of medical staff in physiotherapies.

Key words: Cortisol, adrenaline, noradrenaline, medical staff, EMR exposure.

Introduction

Stress at work and work related changes in health and well being of the medical staff have been subject to growing concern in recent years (Deane et al. 2002, Elfering et al. 2002, Fujiwara et al. 2004). Little is known about stress at work of the medical staff in physiotherapies, exposed to some common for the medical staff stressors as risk of infections, emotional load of dealing with patients, heavy lifting, exposure to chemicals, but also some specific stressors as the exposure to electromagnetic radiation (EMR) from different devices as equipment for microwave and high frequency diathermy, pulsed magnets, d'Arsonvale devices, optical sources (UV, IR and visible), lasers etc.

Several studies investigated the effects of radiofrequency EMR emitted from GSM, broadcasting and TV transmitters on hypothalamic-pituitary adrenal axis and sympathetic adrenomedullary system. Mann et al. (1998) studied several endocrine parameters in humans exposed at night to a low level (0.2 W/m^2) radiofrequency field from GSM at 900 MHz and found a transient 1 hour increase in cortisol during the first hour of the exposure. Radon et al. (2001) failed to find an effect of low level pulsed radiofrequency EMR (carrier frequency 900 MHz, pulsed frequency 217 Hz, average power flux density of 1 W/m^2) on the salivary cortisol. Our earlier data (Vangelova et al. 2002) showed a trend for increase in 11-oxycorticosteroid (11-OCS) excretion rates in operators, working under low-level radiofrequency EMR. Next our study (Vangelova and Israel 2005) showed dose-effect relationship in the excretion of stress hormones and radiofrequency EMR. There are no data for the effect of EMR on stress hormone reactivity in medical staff in the physiotherapies, exposed to high level EMR, but for very short periods of time.

The **aim** of the investigation was to study the effect of EMR on stress hormone reactivity of medical staff in physiotherapies.

The study is a part of complex investigation of health risk in medical staff exposed to EMR.

Material and methods

Subjects

We investigated 15 female physiotherapists, aged 49.5 ± 7.4 years with average length of service 26.4 ± 7.7 years, working in 4 hospital physiotherapies in Sofia. A control group of nurses, matched by age up to three years, work organization and having similar job task was studied. The control group was of mean age 48.9 ± 6.9 years and length of service 25.8 ± 7.3 years. All the investigated subjects worked fast-rotating two-shift system:

morning shifts (7:30 a. m- 2:00 p.m) and afternoon shifts (1:30 - 08:00 p.m). The investigated subjects have signed informed consent for participation in the study.

EMR exposure and confounding physical factors

EMR exposure

The method for EMR exposure assessment is presented in details elsewhere /9/. In general, the method is based on the following:

Parameters for exposure assessment

In order to establish unified conditions for exposure assessment for different frequencies (over the overall frequency range) we apply a general unified indicator associated with the energetic irradiation dose, according to the ICNIRP Guidelines /8/, ACGIH TLVs /15/, and the Bulgarian National Standards /1,2/.

Conditions for applying the wave impedance

We can consider a prevailing directed flow at distances from the emitter to the object not shorter than 6 wavelengths and an entirely homogeneous flow of electromagnetic energy – at about 100 wavelengths. In the far field the conductivity of the medium is proportional to the squared distance from the emitter. At approaching it the value of this quantity increases proportionally to the volume between the emitter and the object, reaching maximum through areas obtained along the main diagonal of the volume. This reflects on an undefined value of the wave impedance.

Dimensions of values related to energy load

The energy load of the human organism is defined for three cases as a derived quantity of energy falling at external irradiation: $W_E = E^2 \cdot T$, $(V/m)^2 \cdot h$, $W_H = H^2 \cdot T$, $(A/m)^2 \cdot h$ and $W_S = S \cdot T$, $\mu W/cm^2 \cdot h$, based on dispersed energy per unit time on human body during the official working shift. Measurable quantities are used – intensities and power density according to the distance from the generator to the measuring device and the respective frequency range of the single photon.

As **SAR** is introduced by the dimension of base metabolism of an adult man (175 cm/70 kg) the dimension of **SA** is the dimension of **SAR** by the time.

The two types of quantities - W_E , W_H and W_S on the one side, and **SAR**, **SA** on the other do not differ substantially in conditions of air equivalent environment and a human body situated in it.

SAR is introduced through Human Equivalent Antenna. If the respective effective area is A_e , then through relationships between the dimensions of the quantities **W** and **SA** following by the definition for power and from the way of determining human body exposure, the quantity **W** corresponds to whole body value of **SA** at constant body weight and unchanging mean conductivity of the tissue, standardized to the effective exposure area A_e . The magnitude of the latter on its part depends on the mutual orientation of a standing person and the intensity of the falling electric field **E**.

The measurable quantity in all cases is the same – **E** [V/m]. Consequently W_E will incorporate the definition of **SA** and vice versa.

Determination of the exposure duration

We divide the time of being in the working environment with NIR into two sets of intervals for exposure duration: real exposure time at work with a device T_{app} [h], and a total duration of the working shift **T** [h]. The difference between them is so called “void time” when there is no real exposure.

We use the method of the “chronometer scenario” because the void time has no equipartitioned averaged evaluation. The duration time is introduced by the number of devices and the number of patients serviced by the individual.

Measurement method

The method is unified as far as three parts of its nature are unified: Equipment; Distances to the particular device, mandatory for the measurement – 6 distances depending on the frequency range; list with the mandatory restrictions to the behavior of the physicist/engineer, performing the measurement.

The major characteristics of the method are the 6 mandatory distances to the different types of generators determined depending on the frequency range of the radiation. They conform to two conditions: Requirements for measurement in the far and near field zones; Requirements for determination of **SAR** in different cases of electromagnetic energy falling on a standing human.

General relationships for assessment of individual exposure

The dose is a function of the squared mean measured intensity and can be presented by the **SAR** quantity.

Our calculation formulation is based on the vision of the averaged dose: the dose (calculated with the actual measured values of the field and exposure time) multiplied by the mean geometric value of the partial doses on

STRESS HORMONE REACTIVITY UNDER EMR

the distance from the physician/nurse to the patient r_i and the dose of the same to another characteristic distance (one of the cited – r_i , $i \neq 1$). Thus a characterizing quantity is obtained which is a non-dimensional growing sum \bar{D} :

$$\bar{D} \approx \sum \frac{1}{q} \sqrt{D(r_i)} \sqrt{D(r_{i \neq 1})}$$

Here I/q is a non-dimensional quantity – ratio.

The squared field strength (E^2) used for the dose assessment is equal to the product of the measured intensity of the field at distance r_i and the sum of weighed intensities of the other 5 distances.

The method allows, at unified measurements, the elaboration of individual exposure assessment for each person in physiotherapy through calculations depending on the number of devices, number of patients and the actual configuration of the ward.

SAR is calculated for the relevant frequency directly through the calculated dose multiplied by the individual's mass:

$$SAR = D \cdot m + B(f) + C ,$$

where m is the mass of the exposed person; B is a frequency -depending ratio, and C is a constant.

The method was used for assessment of the exposure in several physiotherapy units. Assessment of the exposure in several physiotherapy units by devices is shown on Table 1. Calculating the relative values for the whole frequency range in the studied physiotherapies the obtained quota is much larger than 1.

Table 1

Frequency	Devices	Calculated parameter	Basic restriction
≤ 2 kHz	Magnets	$j \approx 0,28 - 0,31 \text{ A/m}^2$	$j \leq 2 \text{ mA/m}^2$
≤ 2 kHz	Interferentz	$j \approx 0.69 \text{ mA/m}^2$	$j \leq 2 \text{ mA/m}^2$
$f \leq 2.5$ MHz	UHF generator for ultrasound therapy	$j \approx 3.8 \text{ mA/m}^2$	$j \leq 2 \text{ mA/m}^2$
≤ 100 kHz	Diadynamik (Bulgaria)	$j \approx 0.15 \text{ mA/m}^2$	$j \leq 1 \text{ A/m}^2$
≤ 100 kHz	Galvanostat	$j \approx 0.15 \text{ mA/m}^2$	$j \leq 1 \text{ A/m}^2$
$150 \div 300$ kHz	D'Arsonval	$SAR \leq 0.4 \text{ W/kg}$	$0,4 \text{ W/kg}$
$27,12$ MHz	UHF devices	$SAR = 3,71 - 9,78 \text{ W/kg}$	$0,4 \text{ W/kg}$
2450 MHz	Medical radar	$SAR = 0,31 - 5,3 \text{ W/kg}$	$0,4 \text{ W/kg}$ whole body 20 W/kg for limbs 10 W/kg for head

Light sources (polychromatic) - restrictions according to ACGIH (2004):

IR: $S \leq 1.8 \cdot t^{3/4} \text{ W/cm}^2$ (for cornea and lens)

IR: $S \leq 0.6/\alpha \text{ W/cm}^2 \cdot \text{sr}$ (for retina protection)

IR (with blue light filter – B1): $1 \mu\text{W/cm}^2$, and : $t_{\max} \leq 10 \text{ (mJ/cm}^2\text{)}/S(\text{W/cm}^2)$

UV and visible light: $t_{\max} \leq 0.003 \text{ (J/cm}^2\text{)}/S \text{ (W/cm}^2)$

Quartz (UVB-1, UVB, UVA, Visible: $S \approx 17.6 \text{ mW/cm}^2$

Solux Infrarouge, without filters: $S \approx 286.1 \text{ mW/cm}^2$

Solux Infrarouge, with filter B1: $S \approx 4.9 \text{ mW/cm}^2$

Noise and microclimate

The noise and microclimate were followed, too, and were within hygienic norms with no differences between the groups.

The psychosocial factors

The psychosocial factors were assessed by the questionnaire “My job”, based on checklists, containing five subscales (Kompier et al. 1994). The working condition scale contains items about work posture, lighting, noise, vibrations, temperature, humidity, flow, dust, odours, etc. The job content scale sums eighteen items as a monotony, tasks, requiring intense concentration, time pressure, work organization, etc.). The job control scale (ten items) includes questions about novelties at work, ability to influence the pace, methods of work, promotion, etc. The work related social support scale sums ten items: five ones concerning support from coworkers and five from supervisors. Health complaints scale is the sum of sixteen items.

The excretion rates of stress hormones

The excretion rates of stress hormones were followed during the morning shift (7:30 – 14:00). The following

three periods were studied: early morning (6:30 – 8:30), second period (8:30 – 11:00) and third period (11:00 – 13:30). The urine aliquids were stored at -20°C and the subsamples for catecholamine assay were acidified to pH 3 with 6N HCL prior refrigeration. Urine free cortisol was assessed by radioimmunological kit (Orion Diagnostica, Espoo, Finland): interassay CV 5.2, 5.2, 6.1 % for low, mean and high value urine samples. The catecholamines adrenaline and noradrenaline were measured with spectrofluorimetric method (Vangelova 2000).

Statistics

The time-of-day variations of the studied stress hormones were analyzed for the effect of radiofrequency EMR exposure and time-of-day by tests of between-subjects effects (SPSS). Variation analysis (one-way ANOVA) and correlation analysis were used to calculate the psychosocial factors and the relationships between the studied variables.

Results

Our data show no significant differences of psychosocial factors between the exposed and control group (Table 2). The studied physiotherapists and control group of nurses had a feeling of strain at work and emotional load of dealing with patients, increased risk of infections, heavy lifting and work tasks, requiring concentration. The working conditions were described as moderate, but the physiotherapists found the lighting unsatisfactory. The number of psychosomatic complaints were comparatively high with both studied groups, slightly higher with the physiotherapists in comparison to the control group of nurses. The main psychosomatic complaints were musculoskeletal disorders (pain in the back, bones and muscles), numbness and/or tingling sensation in the limbs, physical and mental exhaustion, fatigue, dizziness, etc.

Table 2.

The psychosocial factors in exposed to EMR physiotherapists and control group

Scales/Groups	Maximal scores	Physiotherapists	Control group (nurses)
Working conditions	17	7.1 ± 3.0	7.1 ± 9.8
Work content	16	5.4 ± 3.2	7.0 ± 3.2
Control	10	2.9 ± 2.02	5.3 ± 1.8
Social support	10	2.3 ± 1.9	2.6 ± 2.4
Psychosomatic complains	16	9.4 ± 3.3	8.9 ± 2.7

Significantly higher excretion of cortisol with the physiotherapists in comparison to the control group of nurses (Figure 1) was found ($F_{(1,69)} = 7.171$, $p = 0.009$). The excretion rates of cortisol followed the typical diurnal rhythm with highly significant time-of-day variations ($F_{(2,69)} = 12.231$, $p = 0.000$).

The adrenaline excretion rates (Figure 2) were significantly higher in the studied physiotherapists in comparison to the control group of nurses ($F_{(1,69)} = 7.869$, $p = 0.007$). Also, significantly higher excretion rates of noradrenaline (Figure 3) with the physiotherapists in comparison to the nurses ($F_{(1,69)} = 10.643$, $p = 0.002$) were found. The time-of-day variations of adrenaline and noradrenaline were not significant.

Figure 1. The excretion rates of cortisol in physiotherapists exposed to EMR and control group.

Figure 2. The excretion rates of adrenaline in physiotherapists exposed to EMR and control group.

Figure 3. The excretion rates of noradrenaline in physiotherapists exposed to EMR and control group.

Discussion

Our data show significant effect of non-ionising radiation on the excretion rates of stress hormones during the working day. The work conditions, work content, work control and psychosocial support showed no significant differences between the exposed and control group. No acute incidents and changes in the task requirements among the groups during the period of the study were registered. The number of treatments in the studied physiotherapies did not exceed the number of treatment by the studied control group of nurses. The studied physiotherapist had no complains concerning the EMR emissions and were not aware of the level of the exposure during the study.

The present study confirmed our previous data (Vangelova et al. 2002, Vangelova and Israel 2005) for effect of EMR exposure on stress hormones reactivity, with the highest effect on noradrenaline excretion rates. The stress hormones are important biomarkers for allostatic load (McEwen 1998, Chrousos 2000, Tsigos and Chrousos 2002) and the long term effects of increased secretion of stress hormones are associated with health implications. The effects of catecholamines on the cardiovascular function are well known. The excessive and sustained cortisol secretion has been for long associated with depression, osteoporosis, immunosuppression and the entire spectrum of the metabolic syndrome (Fraser et al. 1999, Rosmond et al 1998).

Summing up, significantly higher excretion rates of stress hormones with the medical staff under EMR exposure in physiotherapies were found. As outlined above, the chronic elevation of stress hormones may be associated with health implications. Reduction of EMR exposure in physiotherapies both by technical solutions and limiting the time of exposure should be encouraged.

EFFECTS OF ELF-EMF EXPOSURE ON BODY WEIGHT GAIN, HAEMOPOIESIS AND MAMMARY CARCINOGENESIS IN BALB/c and BALB NeuT MICE.

ABSTRACT

Several epidemiological studies have pointed to a positive correlation between Extremely Low Frequency ElectroMagnetic Fields (ELF-EMFs) exposure and the incidence of haematological or solid tumors. To better clarify its effects on haemopoiesis and cancer development, we exposed to continuous and intermittent ELF-EMF young and adult BALB/c mice or inbred BALB Neu T mice: the latter constitute a transgenic model of HER-2-dependent mammary carcinogenesis. We monitored the body weight trend and studied haemopoietic lineages and mature immune cells in bone marrow and lymphoid organs by morphologic and FACS analysis.

In young but not in adult male and female BALB/c mice there was a transient decrease of body weight and a decrease in bone marrow and splenic myelopoietic cells, whereas there were no haematological differences between treated and control young or adult BALB NeuT mice, probably because of the cancer-driven haematological dysregulation. Histological and Whole Mount grading showed that ELF-EMF do not influence mammary carcinogenesis.

This study demonstrates that ELF-EMF produce a biological stress that affects growth. Healthy subjects are able to both adapt to and compensate it. Further in vivo studies are needed to determine the consequences of ELF-EMFs exposure combined with other known stress factors.

INTRODUCTION

There is a large body of epidemiological evidence in favour of a significant positive correlation between exposure to magnetic fields and the risk of cancer [1, 2, 3, 4, 5] and the International Agency for Research on Cancer (IARC) has classified extremely low frequency electro) magnetic fields (ELF-EMF) as possible sources of human cancer [6]. Subsequent in vitro, in vivo and epidemiological studies, however, have not yet substantiated this correlation and its extent.

Carcinogenesis is a complex process and ELF-EMFs could be involved in any of its steps [7]. They do not induce direct DNA damage in vitro, but may synergize with compounds that induce DNA modification [8]. It has been shown, for example, that ELF-EMFs exposure co-promotes the rat mammary tumors induced by 7,12-dimethylbenz[a]anthracene (DMBA) [9, 10].

The central role of the immune system in the natural history of carcinogenesis makes it essential to determine the immunological consequences of exposure to ELF-EMFs. Some studies show that ELF-EMFs have no effect on or do not suppress the immune system, whereas others have found proliferative effects. Exposure of murine bone marrow cells to a magnetic field causes proliferation and differentiation/reduction of the granulocyte-macrophage progenitor, whereas its effect on the proliferation of stromal stem cells proliferation is not clear [11]. Leukopenia and neutropenia have been observed in mice after long exposure to ELF-EMFs [12]. In another report, ELF-EMFs had no effect on the cytotoxic activities of NK and LAK cells, nor on the production of IFN- γ , TNF- α , IL-2 and IL-10 production by human PBMC [13].

These discrepancies can readily be assigned to the use of dissimilar cell systems, mouse models, magnetic flux

IEZZI M., FELICETTI P., BORGIA L., PANNELLINI T., MARIGGIO' M.A.,
PIETRANGELO A, MEZZETTI A., CUCCURULLO F., FANO' G., MUSIANI P.

densities, and exposure units and periods.

The present study set out to determine whether a striking relationship exists between carcinogenesis and exposure to ELF-EMF, and how far the immune system is affected.

A pair of Helmholtz coils was used to deliver variable, homogeneous, sine-wave AC magnetic fields at 50 Hz with an intensity of 0.5-1.0 mT. The apparatus comprises plastic cages in which the animals are exposed to the ELF-EMFs and is located in an insulated room with the control animals outside the EMF area (see appendix- Instrument). BALB/c and BALB NeuT mice were employed. BALB/c is one of the most frequently used inbred strains owing to its good breeding performance and long reproductive lifespan. It is particularly well known for the production of plasmacytomas on injection of mineral oil and widely used for studies on lymphoma.

BALB-neuT are transgenic for the rat transforming HER-2/neu oncogene [14, 15]. Its transforming mutated form under the transcriptional control of a mammary tumour virus causes fast and aggressive mammary carcinogenesis. Tumours become spontaneously evident after the progression of tumorigenesis and their relationship with the surrounding tissues is preserved. Reproduction of the development of autologous tumours, the occurrence of invasion and metastasis, and the presence of an intact immune system are other key features of these genetically modified mice [16]. At 10 weeks of age, they display advanced cancerization, especially around the nipple where the side buds become in situ carcinomas and an increasing number of hyperplastic foci form along the mammary tree. The in situ carcinomas become invasive between the 15th and the 20th week and metastasize after the 30th week [17].

Our experiment was designed to answer the following questions.

Initially:

- * Whether ELF-EMFs influence the growth and the haemopoietic system of BALB/c and BALB NeuT mice
- * Whether male and female animals are equally responsive
- * Whether young and adult animals are equally responsive

Subsequently:

- * Whether the effects were transient or persistent
- * Whether a dose-response relation or a threshold value for the ELF-EMF intensity is apparent
- * Whether continuous and intermittent (night-time only) exposure exert the same effects

Lastly the effect of ELF-EMFs effect on mammary carcinogenesis in BALB NeuT mice was investigated.

Mice were randomised as explained in the Appendix. Briefly, groups of female and male BALB/c and female BALB-neuT were exposed continuously and intermittently to ELF-EMF at 0.5 or 1mT at 6 weeks of age (young mice) and 10 weeks of age (adult mice).

Animal body weight was recorded at the beginning of the experiment and every 15 days.

After 4 and 12 weeks from the beginning of the exposure mice were sacrificed and primary and secondary lymphoid organs were analyzed by histology, immunohistochemistry and flow cytometry.

Tumour burden in BALB neuT mice was assessed by Whole Mount analysis, histology and immunohistochemistry.

Since no differences were evident between 0,5 and 1 mT ELF-EMF exposure, only data referring to 0,5 mT will be shown below.

ELF-EMFs slow down the body weight gain of young, but not of adult BALB/c mice.

Young male and female BALB/c mice were treated for 12 weeks. The controls were housed in the same room. Their body weight was recorded at the beginning of the experiment and every 15 days.

After 4 weeks of exposure, a significant decrease in body weight was observed in both continuously and intermittently treated mice (Fig.1, 2). This was made up later.

ELF-EMF EXPOSURE AFFECTS BODY WEIGHT GAIN AND HAEMOPOIESIS IN YOUNG BALB/C MICE.

Fig.1

There was no comparable decrease in the adult animals.

Fig.2

ELF-EMFs impaired bone marrow myelopoiesis and splenic lymphoid compartment in the young BALB/c mice.

Several bone marrow and spleen alterations were found after 4 weeks' exposure.

No comparable changes were noted in the adult animals.

Bone marrow haemopoiesis.

Morphometrical analysis of cytological bone marrow samples showed that myeloid progenitors were reduced in both continuously and intermittently exposed mice (Tab 1). Myelocytes are large cells with specific granules in the cytoplasm and an indented nucleus, usually displaced from the center. Metamyelocytes are similar to the myelocyte stage except that they are smaller and demonstrate a deeply indented, kidney shaped nucleus. In spite of the reduction in the total myeloid compartment (see Segmented cells in Tab 1), the ratio between mature neutrophils and immature myelocytes was normal (data not shown). The decrease of segmented cells was coupled with a relative increment in the proportion of red cells and lymphocytes. However the bone marrow cellularity was normal, as well as the differentiation in all the lineages, so neither maturative blocks nor dysplasia were evident.

Table 1. Bone marrow cell count in 10 week old mice.

	Controls	Intermittent ELF-EMFs exposure	Continuous ELF-EMFs exposure
Myeloid Immature Cells	13 ± 3.1*	8 ± 3.1†	7 ± 4.1†
Segmented cells	33 ± 9.1	23 ± 8†	24 ± 7.1
Erythroid Cells	45 ± 7.3	54 ± 10.6†	53 ± 11.6
Lymphoid Cells	12 ± 5.1	18 ± 3.1	16 ± 6

*The values (mean ± SD from 16 mice per group) are expressed as cell percentages

†Significantly different values (a: $p \leq 0.001$) from those of WT littermates

Histological and immunohistochemical analysis of lymphoid organs.

The volume of the spleens of treated and untreated mice was determined from the following formula: “(transverse diameter)² * longitudinal diameter/transverse diameter”. No differences were found (data not shown). No splenomegaly or other macroscopic pathological aspects were observed.

Despite their normal size, the spleens of treated mice revealed a reduction in the white pulp area (Tab. 2).

Table 2. Extension of the white pulp in the H&E stained spleens.

	Controls	Intermittent ELF-EMFs exposure	Continuous ELF-EMFs exposure
White pulp	52 ± 1.1*	46 ± 2°	43 ± 3°

*The values (mean ± SD from 16 mice per group) are expressed as the percentage of the area occupied by

White pulp area [% = (White pulp area*100)/total spleen area].

° Significantly different values ($P \leq 0.01$) from those of WT littermates.

The same results were obtained when we correlated the CD4, CD8 and B220 positive areas with the total spleen area, showing that the reduction involved all the lymphoid subsets.

No architectural nor cytopathological alterations were observed in the lymphoid (black arrows) or haemopoietic (green arrows) compartments. (Fig.4)

Fig. 4

The percentages of the CD4, CD8 and B220 positive areas in the lymph nodes did not differ in the treated and untreated mice.

The effects of ELF-EMFs exposure on the immune system are reversible.

Bone marrow and spleen samples were collected from the treated and untreated BALB/c mice after 12 weeks. The haematological parameter values of treated mice are not significantly different with respect to the controls. Count of bone marrow cells on cytological smears shown a normalization in percentage of myeloid compartments and quantitation of white pulp area percentage in the spleen showed no differences between experimental groups (data not shown).

FACS analysis of spleen and bone marrow from 18-week-old mice.

To obtain a clearer picture of any slight effects of ELF-EMF, at the end of the treatment we performed FACS analysis of bone marrow and spleen cells at the 18th week of age; a statistically significant reduction in CD11b+ granulocyte and monocyte lineages was observed in the male (Fig. 5, 6), but not the female mice.

ELF-EMF EXPOSURE AFFECTS BODY WEIGHT GAIN AND HAEMOPOIESIS IN YOUNG BALB/C MICE.

Fig 5

Fig 6

ELF-EMFs slow down the body weight gain of young but not of adult BALB/neuT mice.

Young and adult female BALB/neuT mice were exposed the same ELF-EMF for 12 weeks.

After 4 weeks, a slight decrease in body weight was observed in both continuously and intermittently treated young mice. This was made up later.

ELF-EMFs exposure does not affect bone marrow myelopoiesis and splenic lymphoid compartment in young and adult female BALB/neuT mice.

As for BALB/c mice we analyzed hematological parameters as well as the structure of hematopoietic and lymphoid organs. A progressive increase in the number of monocytes and granulocytes was found in the peripheral blood of BALB/neuT mice after 4 and 12 weeks of exposure. Cytological examination of bone marrow smears revealed a predominance of segmented cells when compared to treated or untreated BALB/c mice (Table 3, compare to Table 1), coupled with a relative decrease in the proportion of red cells and lymphocytes.

Table 3 Bone marrow counts in 12-week-old BALB/neuT mice.

	Controls	Discontinuous ELF-EMFs treated mice	Continuous ELF-EMFs treated mice
Myeloid Immature Cells	20 ± 4.1*	21 ± 6.1	24 ± 3.1
Segmented cells	42 ± 9.1	47 ± 3	39 ± 5.1
Erythroid Cells	35 ± 7.3	36 ± 10.6	33 ± 11.6
Lymphoid Cells	10 ± 6.0	12 ± 9.2	14 ± 4.0

At 18 weeks of age, FACS analysis of the spleen and bone marrow revealed a pronounced increase of CD11b+ granulocyte and monocyte lineages in all treated and untreated BALBneuT mice when compared to BALB/c mice. All the alterations were proportional to the tumor burden and not to the treatment.

ELF-EMF exposure does not modify the occurrence and progression of BALB-neuT mammary tumors.

To assess the effects of ELF-EMFs exposure on tumor occurrence and progression, mammary glands of control and treated mice were analysed by Whole Mount preparation, histology and immunohistochemistry.

Fig 7 and 9 show representative whole mount pictures of the inguinal mammary gland from a control (a), a continuously (b) and an intermittently (c) exposed BALB Neu T mouse at 10 and 18 weeks of age. Fig 8 and 10 show their respective histological aspects.

These pictures show that ELF –EMS exposure didn't modify the occurrence, the progression or the histological features of the HER-2 dependent tumors.

ELF-EMF EXPOSURE AFFECTS BODY WEIGHT GAIN AND HAEMOPOIESIS IN YOUNG BALB/C MICE.

SUMMARY

This study was performed on a large number of animals (a total of 720 mice) with an innovative dedicated generator of ELF-EMF to answer the following questions:

- * Whether ELF-EMFs influence the growth and the haemopoietic system of BALB/c mice
- * Whether male and female animals are equally responsive
- * Whether young and adult animals are equally responsive

Our results clearly indicate that ELF-EMF exposure slow down the body weight gain and alter the haemopoietic system of young, but not of adult BALB/c mice resulting more effective on male compared to female animals.

Subsequently we wondered:

- * Whether these effects are transient or persistent
- * Whether a dose-response relation or a threshold value for the ELF-EMF intensity is apparent
- * Whether continuous and intermittent (night-time only) exposure exert the same effects

Interestingly we found that after the first 12 weeks of exposition gain loss and alterations of spleen and bone marrow cell count were almost completely recovered persisting only a reduction of granulocyte and monocyte lineages in the male mice exposed from the young age.

We were not able to find a dose-response relation or a threshold value for the ELF-EMF intensity nor a difference between continuous and intermittent exposure.

Lastly the effect of ELF-EMF exposure on BALB NeuT mice growth, hemopoietic system and mammary carcinogenesis was investigated.

Only a slight loss of weight during the first month of treatment was reproduced in the BALB NeuT system. Spleen and bone marrow cell count as well as tumoral occurrence and growth appeared not to be influenced by ELF-EMF exposition probably because of the aggressiveness of this model of mammary cancerogenesis and of cancer-driven haematological dysregulation.

This study demonstrates that ELF-EMF produce a biological stress that affects weight gain and haemopoiesis of growing mammalian organisms. Healthy subjects are able to both adapt to and compensate it. Further studies are requested to elucidate the role of oncosuppressors or repair systems in this scenario.

ACKNOWLEDGMENTS

APPENDIX

Instrument. The 50Hz electromagnetic fields were generated by a pair of Helmholtz coils. This device was planned and built to deliver variable, homogeneous, sine-wave alternate current magnetic fields with 50 Hz frequency and intensities ranging between 0.1-1.0 mT \pm 2%. The pair of Helmholtz coils, (r=630mm, distance between coils=700mm), parallel to the ground and producing homogeneous magnetic field over the specified volume-under-test corresponding to the plastic cage in which where the animals to be exposed, were located in an isolated room containing also the control animals out of the electromagnetic fields exposure area. The coils were connected to a power supply Elgar Electronics (mod. CW 2501P) and were used to generate 0.1-1.0mT ELF for long time animal exposure (up to 16 weeks).

The Helmholtz coils connected to the power supply

Mice.

Female and male Balb-c and Balb-neuT mice transgenic for the activated rat *neu* oncogene have been generated in our laboratories.

Four-week old females were routinely screened for the transgene by PCR, as previously described ([]Muller Cell 1988).

120 male, 120 female BALB/c and 120 BALB-neuT mice entered the study at 6 and 10 weeks of age. Each group of 120 mice was divided into 3 groups of 40 mice: control group, intermittently exposed group and continuously exposed group. Mice exposed intermittently were exposed during the night only (active period of mice). Half of the

ELF-EMF EXPOSURE AFFECTS BODY WEIGHT GAIN AND HAEMOPOIESIS IN YOUNG BALB/C MICE.

mice were selected for the sacrifice after 4 weeks of exposition. The remaining 20 mice were sacrificed after 12 weeks of treatment. GraphPad Software was used to secure uniform randomization.

All the procedure was repeated twice for the experiments with 0,5mT and 1mT intensity ELF-EMF.

Analysis of body weight trend

Mice were weighted before they entered the study and start the exposition to the ELF-EMF. The body weight was checked each 15 days and the body weight trend was plotted and analyzed by GraphPad.

Blood and bone marrow smear

Peripheral blood was collected via intra-cardiac extraction.

Bone marrow was flushed from femur and tibia and suspended in PBS 1X. A small drop of blood or bone marrow suspension is placed on the surface of a clean glass slide near the end. An edge of the spreader slide is placed on the first slide to the left of the drop of blood and is pulled to the edge of the drop. When the smear was completely dried, it was stained by May-Grunwald Giemsa.

Histology and Immunohistochemistry

For histologic evaluation, tissue samples were fixed in 10% neutral-buffered Formalin, embedded in paraffin, sectioned at 4 μ m, and stained with H&E. For immunohistochemistry, paraffin-embedded or acetone-fixed cryostat sections were immunostained with anti-p185 (clone C-18) (Santa Cruz Biotechnology), anti-proliferative cell nuclear Ag (PCNA) (clone PC10) (DakoCytomation), anti-endothelial cells (CD31, PECAM-1, clone MEC13.3) (BD Pharmingen), anti-Mac-1 (CD11b/CD18, clone M1/70.5), anti-CD8 (Ly/T2, clone YT5 169.4) and anti-CD4 (LT34, clone YT5.191.1.2; all from Sera-Lab, Crawley Down, Sussex, United Kingdom), or anti-CD11c (clone N418; Chemicon International Inc., Temecula, CA), anti-CD45R/B220 (clone RA3-6B2; all from PharMingen, San Diego, CA), Abs. After washing, sections were overlaid with biotinylated goat-anti-rat and anti-rabbit Ig (Vector Laboratories) for 30 min. Unbound Ig was removed by washing, and slides were incubated with avidin-biotin complex/alkaline phosphatase (DakoCytomation). To quantify germinal centers (GC), each spleen was transversely dissected into four segments from which semiserial sections were obtained. The GC in the total area of each section were counted. Morphologic studies were conducted independently by three pathologists in a blind fashion.

Whole mount and image analysis

Whole mounts of all mammary glands were done as indicated in <http://ccm.ucdavis.edu/tgmouse/HistoLab/wholmt1.htm>. Digital images were acquired by dividing the whole mount of each gland into 10 quadrants. Ten points were randomly chosen on the duct surface in each quadrant and the corresponding lesions were measured. All lesions with a diameter >150 μ m on the same quadrant were counted. Images of whole-mount preparations were taken with a Nikon Coolpix 950 digital camera (Nital Spa, Turin, Italy) mounted on a stereoscopic Leica MZ 6 microscope (Leica Microsystems, Milan, Italy). A 0.63 objective were used to obtain images with a total magnification of x630 and a resolution of 1,600 x 1,200 pixels. Images were acquired within Adobe Photoshop version 6.0 graphic software (Adobe Systems, San Jose, CA). Glands larger than a single imaging area were captured by photographing contiguous microscopic fields in a raster pattern. Each captured image was merged using the layer technique in Adobe Photoshop to form a single composite image for analysis. Spatial calibration was determined by photographing a 1 mm stage using the same parameters as those for image capturing of whole-mount preparations. The distance drawn on the 1 mm calibration image was divided by 1,000 to find the number of pixels per micrometer. In each image, 100 discrete points were randomly chosen on the duct surface and lesion widths in micrometer were measured perpendicular to duct direction. Points with no lesion were ranked as zero. Lesion measurements were recorded on an Excel spreadsheet and mean and SE were calculated for each treatment group. Statistics were obtained with a two-tailed Student's *t* test.

Flow Cytometry

Single cell suspensions of bone marrow and spleen were prepared. The cells were washed in PBS with 1%FCS (staining buffer). Aliquots of $0.5-1.0 \times 10^6$ cells were then stained for 30 min on ice with monoclonal antibodies conjugated with fluorescein isothiocyanate (FITC) or phycoerythrin (PE). The antibodies used in these experiments included reagents specific for: B220 (CD45R), TER-119, CD4, CD8 α , MHC-classII (all antibodies were purchased from Miltenyi). Cells were washed once in staining buffer and multicolor flow-cytometric analysis was done with a FACScan (Becton-Dickinson). A minimum of 10 000 events were acquired and the data was analyzed using CellQuest software. Statistics were obtained with two-tailed Student's *t* test.

SUPPRESSION OF NO PRODUCTION IN MACROPHAGES BY ELF ELECTRO-STIMULATION

HOKKAIDO UNIVERSITY***

Abstract

We have pursued the possibility to control immune functions by ELF electro-stimulation. As the first step, the effect of electro-stimulation on the NO producing ability of macrophages was examined. The decrease of NO production due to the electro-stimulation was observed with statistical significance. To elucidate the mechanism of this phenomenon, the amount of the NO synthesizing enzyme was measured. The measurement showed the decrease in the emergence of the enzyme with statistical significance, as well. These facts suggested that the ELF electro-stimulation suppressed the emergence of the NO synthesizing enzyme and that the amount of NO production was consequently decreased by the electro-stimulation. To analyse the association between the amount of the NO synthesizing enzyme and the amount of NO production, the dose-response of this effect was investigated by changing the electric current density of the electro-stimulation. The rates of the decrease in NO synthesizing enzyme and the NO production were found to be very close. These results showed that the change in the NO synthesizing enzyme is closely involved in the mechanism of the suppression of NO production by electro-stimulation. This suggested the feasibility to control the immune function by applying electro-stimulation from outside the body.

Introduction

The influence of ELF electromagnetic field on various physiological functions has been reported, and much study has been conducted mainly from the view point of adverse effects. On the other hand, there is a clinical application such as therapeutic instruments using ELF electric field. With the view towards the immune control by ELF electric field exposure, we have studied the effect of electro-stimulation on cell functions. Macrophages play important roles in a human immune system. We have examined the effect of electro-stimulation on the phagocytic activity and the active oxygen production ability of macrophages. Through this study, it has been found that the both activities are suppressed by the capacitively coupled electro-stimulation^[1,2]. The electric current induced in the suspension of cells was in the similar order to that induced in the human body with the therapeutic instrument of electric field exposure.

In the current study, we have examined the effect of electro-stimulation on the production capacity of nitric oxide (NO). The NO is a kind of the same radicals as the active oxygen and is produced in the immune function of a macrophage. The NO is produced to kill bacteria but can destroy normal cells when produced excessively. Moreover, it reacts with the active oxygen and becomes the peroxynitrite (ONOO⁻). The ONOO⁻ is more toxic and damages normal cells. Therefore, if we can control the NO production, it will contribute to the prevention and the treatment of various diseases. We have examined this possibility by the ELF electro-stimulation in vitro.

Materials and Methods

macrophage preparation

Peritoneal exudate macrophages were used in all the experiments. The thioglycollate medium (4.05%, 2 ml) was injected in the peritoneal cavity of a normal mouse (Std:ddy, female, 7-11weeks). After 3 or 4 days, the cells were harvested from the mouse abdomen. Then, macrophages were collected from the cells in the established method.^[3] We prepared the cell culture solution (RPMI 1640 with L-Glutamine, Sodium Bicarbonate and 10% Fetal Bovine Serum: RPMI 1640, hereafter) with 0.5×10^5 IU penicillin G potassium and 50mg streptomycin sulfate added. The collected macrophages were suspended in the cell culture solution to make the cell density of 2×10^6 cells/ml. When electro-stimulation was applied to the cells, the IFN- γ (10U/ml) and the LPS (1 μ g/ml) were added as stimulants to both the stimulation group and sham group.

electrostimulation system

The macrophage cells were stimulated by the electric current in the container insulated electrically from the electrodes to simulate the condition of electro-stimulation from outside the human body. Figure 1 shows the structure of the sample container.

Two plane electrodes were kept parallel with 3 mm distance by a plexiglass separator. The electrodes were square copper plates (24mm×24mm×6mm top and 32mm×32mm×6mm bottom). The top electrode was insulated with a 0.15 mm thick cover-glass, and the bottom one with 0.10 mm thick silicone film. The outline of the electrostimulation system is shown in Fig.2. Two electrodes were connected to a high-voltage power source through a noise filter. As the power source, the power supply of a commercial apparatus for the electric field therapy was used (Healthtron, Hakuju Inst. Health Science, maximum supply voltage 10kV). A sinusoidal AC signal of 50Hz was supplied to the apparatus with a waveform generator to make the high-voltage with the sinusoidal waveform of 50Hz. In the experiment, the cell suspension was placed in the container, and electro-stimulation was applied in a CO₂ incubator (38°C, CO₂5%). The cell suspension of the sham group was kept in another incubator of the same condition.

Fig.1 Sample container

Fig.2 Schematic diagram of electro-stimulation system.

Effect on NO production

We stimulated macrophages in the suspension with IFN- γ and LPS, and applied the electro-stimulation for the exposure group. The sham group was treated in the same way except connecting to the power source. The amount of NO produced outside the cell was measured as fluorescent intensity (495nm excitation and 515nm emission) using fluorescent reagent Diaminofluorescein-2(DAF-2) for the NO detection.

Macrophages were collected in the established method, and washed three times with Hanks' Balanced Salt Solution (HBSS) in centrifugation (400G) for 5 minutes. Then, they were suspended in the culture liquid RPMI 1640 again, and the electro-stimulation (50Hz, 35 μ A/cm², 16h) was applied. After the electro-stimulation, the macrophages were washed with HBSS in centrifugation, and cultured in HBSS suspension with DAF-2(10 μ M) and L-arginine(1mM) two hours without electro-stimulation. After the two hour culturing, the supernatant part was separated in centrifugation. With a fluorescent photometer, the fluorescent spectrum of the supernatant was measured. The supernatant of the sham group was collected in the same process except for the electro-stimulation, and the fluorescent spectrum was measured in the same way as the stimulation group.

Figure 3 shows an example of the measured result. The abscissa is the wavelength and the ordinate is the fluorescent intensity. The wavelength of the intensity peak was around 515 nm in both cases. There was no significant change in the shape of the spectrum, but 30% decrease in the intensity was observed in the stimulation group. This suggests the suppression of NO production by the electro-stimulation. The same experiments were repeated nine times. Figure 4 shows the reduction ratios of the fluorescent intensity between the stimulation and the sham groups. In all the nine cases, the fluorescent intensity was decreased by the electro-stimulation. The p-value of the paired-t test was 1.79×10^{-2} , which suggested the suppression of NO production by the electro-stimulation with a statistical significance.

Fig.3. Example of measured NO production by fluorescence spectroscopy.

Fig.4 Suppression of NO production.

Effect on iNOS expression

NO is synthesized in a macrophage by the inducible nitric oxide synthase (iNOS). To elucidate the mechanism of the suppression in the NO production, the effect of the electro-stimulation on the iNOS expression was examined. The amount of the iNOS expression was evaluated by measuring the fluorescent intensity in the indirect immunity fluorescent method.^[5, 6]

In the same way as the one mentioned above, macrophages were collected, separated into two groups, and electro-stimulation (50Hz, 35 μ A/cm², 16h) was applied to the stimulation group. After the electro-stimulation, the macrophages were collected in the centrifugation. With 70% ethanol, the cell membrane was processed to enhance its permeation. After three times centrifugation (400G, 5 minutes), macrophages were suspended in HBSS. We added the rabbit anti-iNOS antibody (BD Biosciences) and kept it in a shaker bath at 4 °C in 30 minutes. Then we added 20 μ g/ml of the FITC tagged hircine anti-rabbit Ig antibody (MP Biomedicals Inc.) and kept it in the shaker bath. Finally, we fixed the suspension with 1% paraformaldehyde, and measured the fluorescent intensity with a flow cytometer (FACS Calibur Becton Dickinson and Company).

Figure 5 shows an example of the results. The abscissa is the fluorescent intensity in an arbitrary unit, and the ordinate is the number of the cell. The broken line in the figure shows the average intensity of all the cells. The average values were 79 and 65 for the sham (a) and the stimulation (b) cases, respectively. This result showed the decrease in iNOS expression by the electro-stimulation. The same experiments were repeated eleven times. Figure 6 shows the ratio of the average intensity between the stimulation and the sham cases. As shown in the figure, the decrease in fluorescent intensity was observed in all the eleven trials. The p-value of the paired-t test was 5.52×10^{-5} . This suggested that the iNOS expression was suppressed by the electro-stimulation with statistical significance.

Fig.5 Example of measured iNOS expression by fluorescence spectroscopy.

Fig.6 Suppression of iNOS expression.

Analysis of dose-response

As the first step of quantitative evaluation, the dose-response of these phenomena was analysed. In experiments, the amounts of the NO production and the iNOS expression in different current densities ($0.35\mu\text{A}/\text{cm}^2$, $0.675\mu\text{A}/\text{cm}^2$, $3.5\mu\text{A}/\text{cm}^2$) were measured. After the electro-stimulation in 16 hours, the cell suspension was divided into two. One was used for the measurement of the NO production, and another is for that of iNOS expression. Figure 7 shows the results of the measurements. The abscissa is the current density and the ordinate is the fluorescent intensity normalized by that of the sham case. The number of repeated measurements were 4, 6 and 4 for the cases of $0.35\mu\text{A}/\text{cm}^2$, $0.675\mu\text{A}/\text{cm}^2$ and $3.5\mu\text{A}/\text{cm}^2$, respectively. The result of $35\mu\text{A}/\text{cm}^2$ case was added, in which the numbers of the repeated experiments were 11 and 9 for NO and iNOS cases, respectively.

With the current density of $0.35\mu\text{A}/\text{cm}^2$, we could not observe apparent decrease in either of the NO or the iNOS. With $0.675\mu\text{A}/\text{cm}^2$, about 5% decrease was observed. With the current density of more than $3.5\mu\text{A}/\text{cm}^2$, more than 15% decrease was observed. In both of the NO and the iNOS, the threshold of the suppression seems to exist between $0.35\mu\text{A}/\text{cm}^2$ and $3.5\mu\text{A}/\text{cm}^2$. The similar characteristics in the dose-response strongly suggested the close correlation between the suppression of iNOS expression and that of NO production.

Fig.7 Analysis of NO and iNOS suppression effect by electro-stimulation.

Discussion

In the in-vitro experiments, it was found that the NO production is significantly suppressed by the ELF electro-stimulation. This suggested the possibility to control the functions of macrophages by the electro-stimulation applied from outside the body using the apparatus for the electric field therapy. Since a macrophage plays an important role in the first stage of the immune response, the electro-stimulation can influence the entire immune reaction. For example, we can expect the relief from the following diseases. They include the chronic inflammation and the autoimmune diseases caused by an excessive immune response. We can also expect the relief from the endotoxin shock due to the excessive NO production, the etiologic vasodilation, the cardiovascular ischemia, the cerebral hemorrhage and the cancers. Moreover, we have confirmed the suppression of the active oxygen production by the electro-stimulation.^[2] Therefore, we can also expect the control of ONOO^- .

production which shows high cell-toxicity.

However, the finding of this study is only the result of in-vitro experiments using macrophages. We need further investigation to confirm this effect with human macrophages, and the investigation on this effect in-vivo where other kinds of cells are closely interacted. Yoshikawa and his co-workers reported the increase of NO production in the liver when LPS (2 mg/kg) was administered by abdominal injection and the magnetic field (60Hz, 0.1mT) was exposed in 5.5 hours. The current density induced by this magnetic field inside the body is estimated at $1.1 \times 10^{-8} \text{ A/cm}^2$. This result is opposite to our result. It seems that the direct comparison between these two cases is not appropriate, since the object cell and the current density is greatly different among them.

Besides this, there have been few reports on the effect of ELF electromagnetic fields on the NO production, and little has been known on its mechanism. We consider that the arginine metabolism, iNOS activity and iNOS expression are closely associated with the decrease in the NO production. To investigate this mechanism, we have compared the amounts of NO production and the iNOS expression.

Figure 7 shows the coincidence in the reduction ratio of fluorescent intensity between NO and iNOS by the same electro-stimulation. This result suggests that the electro-stimulation affects the NO production through iNOS expression. The signal transmission pathway for the iNOS expression is stimulated by LPS and IFN- γ through receptors on a cell membrane. As the result, a transcription factor is activated and the iNOS is transcribed. In our study, the electro-stimulation was applied from the beginning when we started the stimulation with LPS and IFN- γ . Therefore, it is most plausible that the electro-stimulation affects this process.

However, the following possibility cannot be neglected. In the peritoneal exudate cells used in this study, about 10% cells were not macrophages. Since these non-macrophage cells can affect the signal transmission pathway of the NO production, they might influence the mechanism of the suppression of the NO production. Therefore, we have to examine this point in the experiment using the pure macrophage cells separated from other cells.

In our experiment, the threshold of the effect was found between $0.35 \mu\text{A/cm}$ and $3.5 \mu\text{A/cm}^2$. In the study for the biological effects of ELF electromagnetic fields, the minimum threshold of magnetic field exposure has been reported.^[7] According to the report, the threshold current density for the characteristic change in tissues and cells was in the order of 10 mA/m^2 or $1 \mu\text{A/cm}^2$. Though this threshold is for the electric current induced by magnetic field, it is very close to our result in which the electric current was induced by the electric field.

Conclusion

With the view toward the control of immune functions by ELF electric field exposure, the effect of the electro-stimulation on the NO production of macrophages was examined in vitro. The decrease of NO production due to the electro-stimulation was observed with statistical significance. In experiments, it was found that the expression of NO synthesizing enzyme or iNOS was suppressed in the same rate as NO in the electro-stimulation. Further investigation is required to ascertain this mechanism of NO suppression and to verify the feasibility of the immune control by electro-stimulation.

Abstract

A hypothesis is proposed how LF EMF treatment can stimulate an immune response, based on recent insights in immunology. Danger signals have been shown in the last decade to be an essential factor in the coordinated response of the immune system to pathogens. We hypothesize that the EMF treatment induces mild stress to cells in the body, which then produce danger signals for the immune system. In this way EMF treatment takes the place of multiplying pathogens and the damage these cause in the triggering of an immune response.

Introduction

Immument has developed a signal for advancing and elevating the immune response to pathogens (multiple LF components, 0.1-50 μ T, 30 minutes per day) which we have tested at various experimental conditions. Pilot findings with this signal (proprietary, but available for research purposes) were presented at the 2004 Kos meeting (Cuppen and Vink 2004). In subsequent experiments with carp, goldfish and chickens significant and often strong effects of immune stimulation have been observed. The effects include: 40% increased oxidative burst of isolated phagocytosing cells ($p < 0.001$), 60% decreased mortality in infected fish ($p < 0.001$), 5% decreased feed consumption for equal growth in chicken ($p < 0.05$) comparable to the use of preventive antibiotics and 40% decreased intestinal lesions in chicken ($p < 0.01$) due to *Eimeria* infections. These results are reported in detail at this conference in one presentation and two posters.

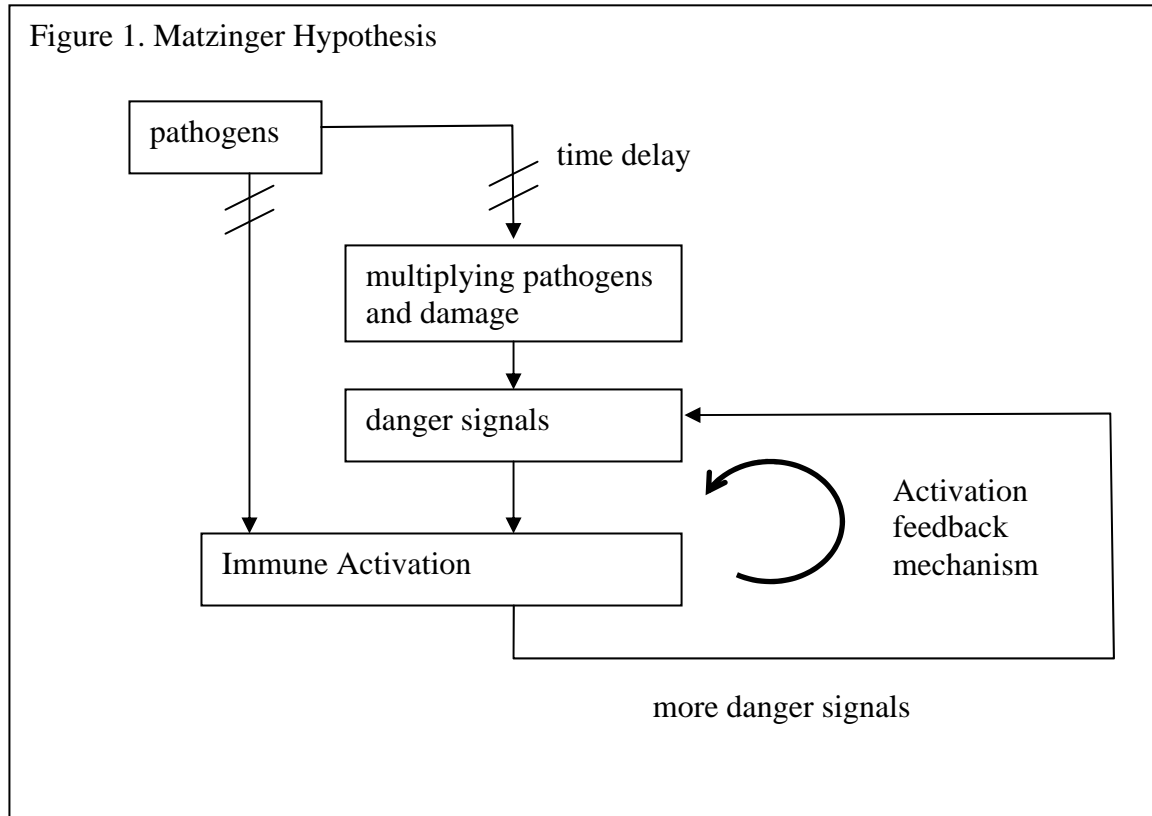

In this paper we take the liberty to hypothesize about the observed strong responses of the immune system of this broad range of animals. The hypothesis regards the possible mechanism of action and attempts to answer the question how such weak, short duration EMF signals can induce an effective immune response.

Hypothesis

During last decade in immunology a hypothesis has been developed that immune response is not only due to the presence of non-self cells but also needs the presence of promoters (e.g. Matzinger 2002, Kapsenberg 2003, Shi et al 2003). This holds in particular for the innate immune response to pathogens not earlier encountered. Such promoters are called “danger” signals. An example might be Heat Shock Proteins (prime examples of cell response to injury or insult), as well as Interferon, Interleukins and other cytokines. Danger signals are formed when cells get stressed or damaged, and this is “presumed by the cells” to be caused by harmful pathogens. The idea behind the view is that strange DNA that does not cause damage, such as a foetus or food, does not and should not trigger an immune response. Support for this view has been obtained from the new approach to transplants that originated from it: after surgery the transplant organ contains lots of danger signals due to the cell damage caused by surgery or the trauma of the donor. Flushing of the transplant organ, which eliminates danger signals from the organ tissue, led to an enormous decrease in rejection reactions from the receiving patient. With this technique, a strong reduction in immune suppressing medication could be achieved. In immunology other factors besides damage due to pathogens have been identified that stimulate the production of danger signals, such as stress or shock from salt, cold or heat. See Engelsma, Hougee and Nap (2003), and Huising, Guichelaar and Hoek (2003).

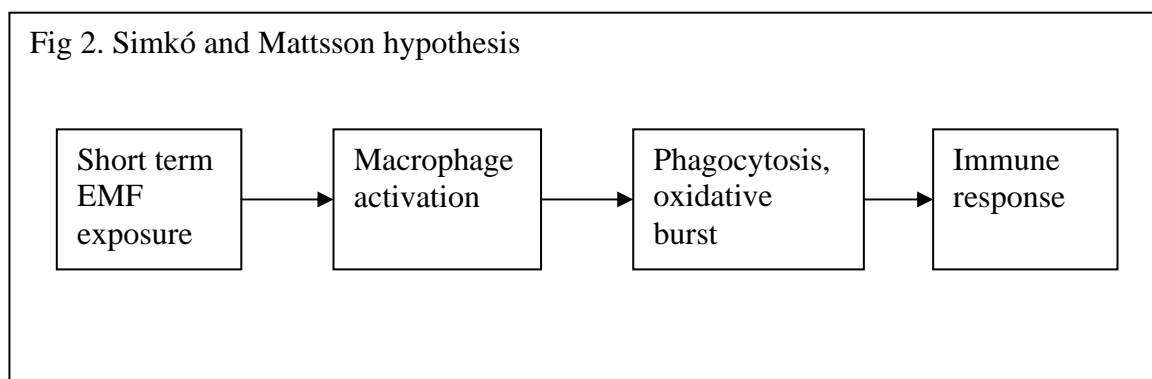

The danger signal hypothesis can be schematically represented as in Figure 1.

Figure 1. Matzinger Hypothesis

Several authors (see Blank, Khorkova, and Goodman 1992, Goodman, Blank and Lin 1994, Blank, Lin and Goodman 1995, Simkó and Mattsson (2004), Monselise, Parola and Kost 2003, de Bruyn and de Jager 1994, Mevissen, Haussler, Szamel, Emmendorffer, Thun-Battersby and Loscher 1998, Markov, Nindl, Hazlewood and Cuppen 2006) discussing the effects initiated by various EMF signals have demonstrated the production of cytokines, increased immune parameters and stress effects and concluded that EMF causes stress at the cellular level and that this leads to production of cytokines and consequently biological response, including immune response. This has led Mattson and Simkó (2004) to formulate a hypothesis that proposes a mechanism for immune activation due to short term EMF exposure (see Figure 2) and a mechanism for cell damage due to long term EMF exposure.

Fig 2. Simkó and Mattsson hypothesis

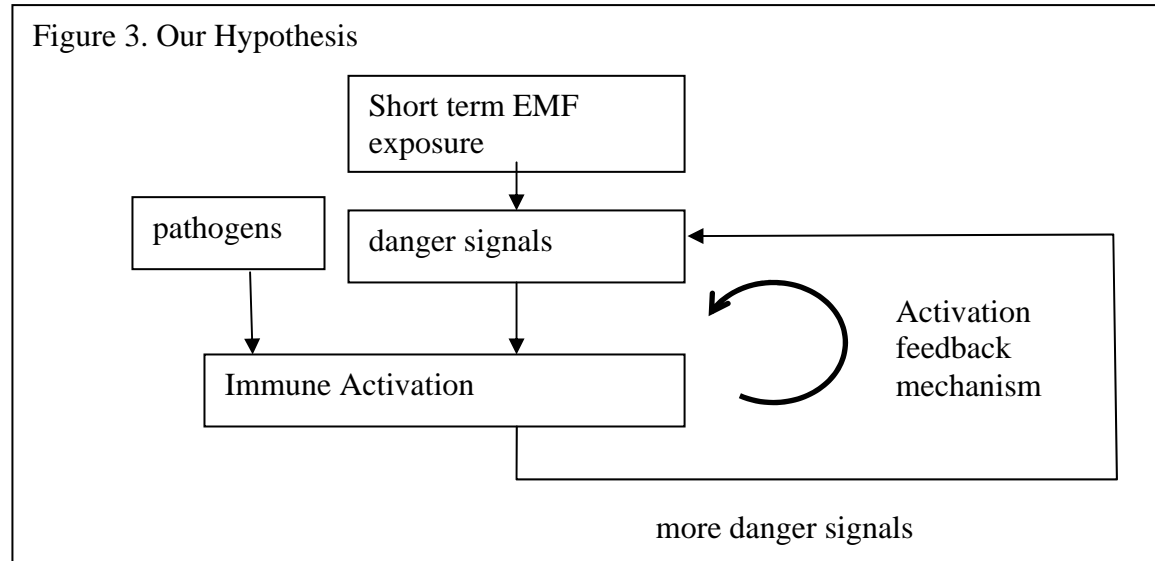

Based on published theoretical and experimental studies, as well as our own experience we propose a hypothesis, that combines and extends the views quoted, by

- the observation that an immune response is a self stimulating process, at least in the initial stages. Macrophages become activated under the influence of danger signals, and thus have a higher statistical chance and a lower expected time until they actually encounter and recognise pathogens. Once this happens they themselves produce cytokines that increase the immune response etcetera
- the observation that for chronic infection apparently the feedback cycle stated in a) does not gain sufficient momentum for the infection to reach acute phase
- the observation that for new infections a more active and alert immune system will start the feedback

loop in a) earlier, thus slowing down the multiplication of pathogens and reducing damage.

Therefore we propose an extended hypothesis which can be schematically represented as in Figure 3.

The core of the proposed Hypothesis is that short term LF EMF exposure, possibly repeated, can produce danger signals that can trigger the immune system activation feedback mechanism in the presence of pathogens. As such the EMF induced danger signals take the place of the danger signals that would be produced by multiplying pathogens and the damage they cause to cells and tissues. In this way a timely EMF treatment can avoid the delay given by the time it takes for enough damage to occur and danger signals to be produced in a normal disease development. Thus the immune response to pathogens can be advanced in time and damage and a well developed pathogen attack can be avoided.

In our own in vivo experiments (Cuppen et al. 2004, 2006c, 2006d) we have observed immune stimulation effects after repeated exposures of 30 minutes per day. There is evidence in literature and there are anecdotal indications that continuous exposure to EMF leads first to increased immune parameters, but later to decreased immune parameters, which can be interpreted as exhaustion (Mevissen et al. 1998, Jager et al. 2004).

Abstract

Most of the publications in the bioelectromagnetics are related to animal/human studies, very few to effects of magnetic fields on plants and practically no studies were performed on small farm animals and fish. Our goal is to examine how properly selected magnetic fields can decrease the potential of development of infectious diseases in farm animals.

Experimental results presented and discussed here are set up to (indirectly) test the hypothesis that low frequency electromagnetic field (LF EMF) treatment can stimulate an immune response through the creation of danger signals which are necessary to trigger an immune reaction in the presence of pathogens.

The reported cell experiments show that the treatment stimulates oxygen burst in phagocytes which supports the notion that danger signals are indeed formed. Experiments with goldfish demonstrate a large decrease of mortality caused by infectious disease (gill parasites and accompanying microbial infections). This result is consistent with the idea that the exposure to EMF increases the strength of the immune reaction, so that a larger percentage of animals sufficiently combats the disease early enough to prevent disease to develop and that these animals are therefore able to return to health. Finally experiments with chicken broilers with coccidia infection, induced after starting the EMF treatment, show both less intestine damage due to the disease and a better growth to feed ratio. This demonstrates the effectiveness of the treatment in prevention of disease: the results indicate that, in the presence of pathogens, a self stimulating immune response originates sooner and more strongly than without the EMF treatment. An infection is then counteracted earlier, with less opportunity for pathogens to multiply and to cause damage.

All results combined support our hypothesis that the Immune LF EMF treatment induces the formation of cytokines (danger signals) that put the immune system in a state of higher alertness and activity.

Introduction

In aquaculture and farming, infectious disease is one of the biggest, if not the biggest problem and challenge, economically as well as in terms of animal welfare and environmental pressure. "Disease is the biggest single impediment to aquaculture development," said Rohana Subasinghe, Senior Fisheries Research Officer at the United Nations' Food and Agriculture Organization (FAO). Total damage in aquaculture of infectious disease is estimated at \$9 billion yearly. In Ecuador in 1999 70% of the crop of farmed shrimp was lost due to a single virus infection that led to a national crisis and a loss of 150.000 jobs.

For chicken farmers infectious diseases form the biggest problem they face. Economically, for animal welfare, environmentally and for acceptance in the market and in society. Preventive antibiotics have been used not only to prevent infectious disease, but also as a growth promoter. The antibiotic use could prevent or eliminate infectious disease at an early stage, before the pathogens strongly multiply in the animals and the animals have to spend substantial energy to combat the disease. In general 5 to 10% decrease of feed necessary to support equal growth could be achieved with preventive antibiotics. However, preventive antibiotics have been banned in Europe from animal feed since 2006, with similar developments in other countries, because of development of microbial resistance related to humans. Therefore the agriculture and aquaculture sectors are urgently searching for other disease inhibitors to substitute antibiotics.

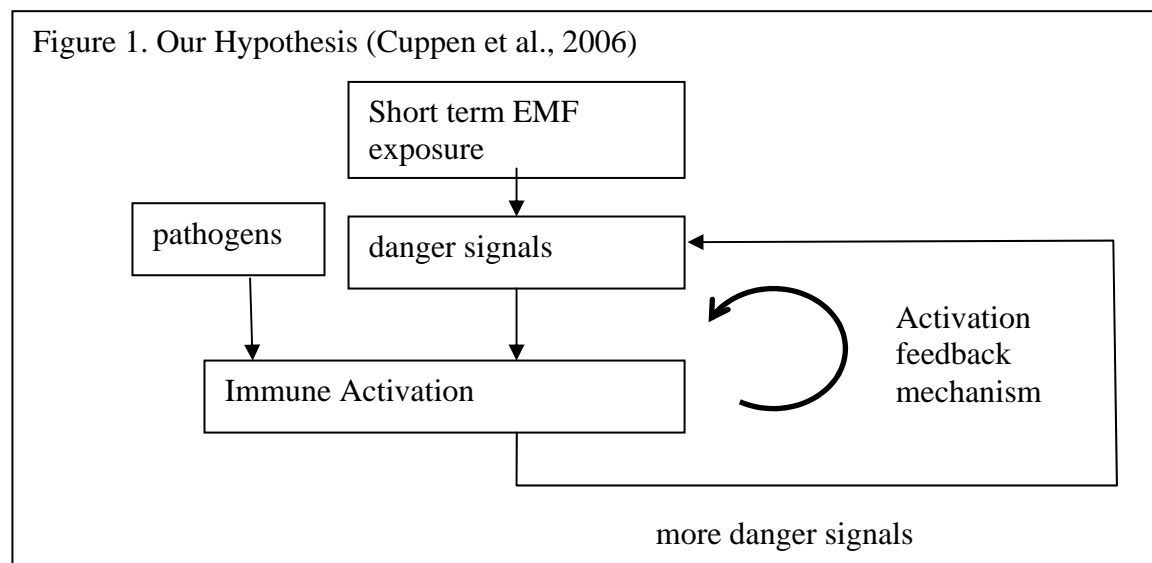

Environmentally, infectious disease causes a lot of pressure: by the chemicals and pharmaceuticals used, by the pathogens that multiply in farms and increase disease pressure on the surrounding wildlife, and by the pressure on aqua farmers to abandon farms with disease and start new farms in nature areas.

It has been shown that various EMF signals are capable of influencing the immune system (Markov, Nindl, Hazlewood, Cuppen, 2006).

Immunent has developed an EMF signal for advancing and elevating the immune response to pathogens (multiple LF components, 0.1-50 μ T, 30 minutes per day) which have been tested at various experimental conditions. Pilot findings with this signal (proprietary, but available for research purposes) were presented at the 2004 Kos meeting (Cuppen and Vink 2004).

In immunology during the last decade the view has been developed that an immune reaction to pathogens needs promoters to be present in addition to the presence of pathogens (or other non-self cells) (Matzinger 2004).

In a companion paper at this conference (Cuppen et al. 2006a) the hypothesis was proposed that the enhanced immune reaction observed after LF EMF treatment is due to the fact that LF EMF induces the formation of such (a level of) danger signals, cytokines such as heat shock proteins (HSP's), Interferon, Interleukins, that an immune response can occur earlier and/or stronger than without the treatment. The treatment triggers the self-sustaining feedback mechanism in the immune reaction which otherwise would occur much later, when pathogens significantly multiplied and caused more damage.

Materials and results

This paper describes three different types of experiments conducted with the Immunent signal applied with different configurations on the subjects of research. For that reason the paper is written in three section describing the methods and results, followed by a discussion section.

In vitro cell experiments

Phagocytes (Macrophages and dendrites) from Carp were isolated as described in (Cuppen et al. 2006c, which also contains detailed descriptions of the other materials and methods) and stimulated in the different ways as described below. Oxygen burst was measured with a NBT assay as a measure of immune activity. and in vitro subjected to the treatment.

In 20 runs 48 samples each were divided over six test groups. Three groups had no chemical pre-stimulation (called negative), three (called positive) received chemical pre-stimulation with 10 μ l 0.01 μ g/ μ l PMA (Phorbol 12-myristate 13-acetate). Pairs of groups were formed (a positive and a negative). One pair was exposed for 30 minutes to sham: called control, one to a signal with 5 μ T field strength: called low, and one to a signal with 1.5 mT field strength: called medium as indicated in Table 1.

Table 1. Summary of the in vitro experiment setup

	No EMF treatment	EMF treatment with field strength	
	Control	5 μ Tesla	1.5 m Tesla
No chemical pre-stimulation	negative control	negative low	negative medium
Pre-stimulation with PMA	positive contr	positive low	positive medium

IMMUNE STIMULATION THROUGH WEAK LF EMF: B. EXPERIMENTS

In each run the 48 samples are taken from a single fish and therefore the oxygen burst activity numbers in different test groups of that same run can be compared to each other. However for different runs different fish are used and the cells of one fish may show large differences in their baseline reactivity and activation capacity to the cells of another fish. Therefore the absolute numbers between different runs are not comparable. This complication can be overcome by normalizing all data to the average negative control value in each run, and positive EMF data to the positive control.

Six out of 20 runs were discarded on the (sole) basis that positive control average did not exceed negative control average by more than 50%. This means that cell preparation must be considered to have failed.

The Oxygen burst was increased in 12 out of 14 cases after 5 μ T treatment (see Figure 2), and in 11 out of 14 cases after 1.5 mT treatment. With pre stimulation with PMA, oxygen burst was further increased in 9 out of 14 cases at 5 μ T, and in 12 out of 14 cases at 1.5 mT.

Figure 2.

All results together are summarized in Table 2.

Table 2. Summary in vitro results, averaged over all runs (Average % increase in oxygen burst.)

	No EMF treatment control	EMF treatment with field strength	
		5 μ Tesla	1.5 m Tesla
no chemical pre-stimulation	negative control = 100%	142 %	133 %
pre-stimulation with PMA	positive control = 276% of negative control	118% of positive control	122% of positive control

Statistical analysis (ANOVA) was carried out with SAS via a meta-analysis of the 14 datasets. A significant ($p < 0.0001$) increase by EMF on the response of the exposed cells was found. As can be seen in Figure 2, the numbers given in Table 2 are averages of strongly varying results. It cannot therefore be concluded that the effect is stronger at 5 μ T than at 1.5 mT or vice versa, but rather that the effects may be of the same order of magnitude at these two field strengths.

A second point we wish to make is that a treatment at or below 5 μ T is in the practice of farm applications (large areas and volumes to be treated) much easier and less costly to achieve than at 1.5 mT.

The data achieved at 1.5 mT are in line with those reported for 50 Hz, sinusoidal, 1 mT fields in murine and human macrophages by Simkó, Droste, Kriehuber and Weiss 2001 and Lupke, Rollwitz and Simkó 2004.

In vivo experiments with diseased goldfish

To evaluate the potential of LF EMF to prevent or decrease the infections caused by ecto parasites (gill parasites) such as *dactylogyrus/gyrodactylus*, *trichodina*, *chilodinella* and *costia* a series of 4 experiments was executed using fantail goldfish (*Carrassius auratus spp.*). Infection with those parasites occurs consistently at the grower and increases during storage, packing and international transport due to crowding. This and

subsequent secondary bacterial infections cause high mortality if not treated. The progress of the diseases can be measured by daily counting and removing from the tank any dead fish over a period of a few weeks. In the reported experiments, running 3 or 4 weeks, fish are divided over 12 to 20 tanks per experiment. Each tank is an experimental unit, and these are divided over a control group (usually 4 tanks) and test groups (usually 4, sometimes 2 tanks each) that are exposed to different EMF treatments, always for 30 minutes per day. In the early experiments we used 12 fish per tank, which was increased first to 21 and then to 30 fish per tank in order to increase the statistical power of the experiments once it became clear that this is feasible.

Tanks are exposed to uniform, vertical AC electromagnetic fields, with a (proprietary) Immune signal consisting of several components with base frequencies between 100 and 10.000 Hz. The treatment is given daily for 30 minutes in each tank, by an automated Immune signal generator that continuously monitors current output that was calibrated to magnetic field strength. For a detailed discussion of materials and methods, and more data, see (Cuppen et al. 2006c) in these proceedings.

The treatment is aimed at boosting the fish immune defense and, thereby, decreasing the mortality. The experiment is powerful because large numbers of animals can be used and the measurement is easy and accurate. For example, results in Figure 3 account for a total of 336 fish in the experiment, 84 in control and 252 in the six experimental series.

In experiments 1 and 2 (see Cuppen 2006c) mortality after 17 days was decreased by LF EMF from $52\% \pm 14\%$ untreated to $19\% \pm 10\%$, and from $52\% \pm 8\%$ untreated to $26\% \pm 19\%$. Moreover the intermediate day values had a comparable ratio to the end values so that the quoted standard deviations probably strongly underestimate statistical significance. In these experiments there were 8 control tanks and 15 experimental tanks at $5 \mu\text{T}$ with 12 fish initially each.

Next, experiments were performed at different field strengths. Figure 3 shows the typical mortality curves in an experiment with 4 control tanks and 2 experimental tanks per field strength with 21 fish initially per tank.

Figure 3 Mortality with treatment on different field strength levels

At only two replicates per field strength these results indicate that the treatment is effective in the whole window of field strength between 0.15 and $50 \mu\text{T}$ (and probably beyond). The average line of all treated tanks (solid, thick) corresponds very well, or is even better than the results of experiments 1 and 2. Together they show that a surprisingly strong improvement of the survival of these fish with this disease can be achieved with this form of EMF.

Because of its interest for practical application in farming and aquaculture, we investigated further at the lower field strength level. Since these field strengths cannot be reliably produced directly in our setup (too low

voltages, too low currents, and therefore too high electronic noise levels) this was done using the stray fields of our coils around tubs at 5 μT . These are solenoid coils which produce the desired field, sufficiently uniform, at 50 cm, 100 cm and 120 cm distance from the (outside) of the coil. Figure 4 gives the results.

Figure 4. Treatment results at extremely low field strengths.

A dose response pattern is visible between 0.003 and 0.06 μT with the latter value delivering a result not far from our reference value of 5 μT .

The results obtained demonstrate that the treatment with EMF drastically reduced the mortality in fish that is due to above-mentioned parasites and secondary microbial infections. These results indicate that even in strongly diseased fish the stimulation with LF EMF mobilizes the immune system for fighting the invaders possibly because it puts the immune system in a higher state of activity, thus giving it a better chance of fighting the disease.

The dose response values given in Figure 4 indicate that some effect of the treatment remains even at field strengths as low as 3 nT. Therefore in experiments large distances must be maintained between control tanks and experimental tanks, so that the stray fields are below 1 nT or less.

This observation raises questions for the experimental setups with sham controls. The field cancellation between the opposing currents in the sham coils must be extremely good. It can be doubted if the required cancellation is ever reached in practice.

Using Helmholtz pairs of coils should also be surrounded with careful measurements of the stray fields, which can be substantial.

In vivo experiments with chicken broilers, exposed to infection pressure from coccidia parasites

A universal infection in fattening chicken is coccidiosis, with *Eimeria* parasites that live and explosively multiply in a particular part of the intestines of a particular host for each *Eimeria* specie. Number of studies has suggested that the immune response to *Eimeria* infection among other is mediated through the release of cytokines. Breed et al. (1997) reported that chicken peripheral blood leucocytes of *E. tenella* infected chickens produce interferon- γ after in vitro re-stimulation. Moreover, it has been shown that treatment chickens with interferon- γ preceding infection with *E. acervulina* decrease the negative effect of infection on weight gain (Lowenthal et al., 1997).

For the three subsequent experiments 192, 288 and 272 one-day old female broilers (Ross 308) were purchased from the hatchery. On day of arrival, they are wing-banded, weighed and randomly housed in wire-floor, suspended cages. Each cage is provided with thick foil and litter. Under the floor of each cage a 16-loop coil was located to deliver LF EMF for 30 minutes per day to chicken within the cage. No attempt was made to create a

uniform field since in a preliminary experiment it was determined that effective field strengths lie between 0.1 μ T and 50 μ T. Moreover the practical application that is our goal will also not allow complete uniformity of the field strengths. The field strength (rms) in the middle of the cage was set at 6,5 micro Tesla, measured with an F.W.Bell 5180 Tesla meter. Dosimetry control during the experiment was ensured by constantly monitoring the (rms) current through the coil. The applied signal was designed by Immune, which contains several LF components with frequencies between 100 and 10.000 Hz.

In the experiment 1, infection pressure was provided with *Campylobacter jejuni* on day 6, in the experiment 2 high level infection pressure was given on day 15 with *Coccidia*, containing a controlled mixture of different *Eimeria* species, and in experiment 3, a low level of the same infection pressure was given at day 15. Detailed information about materials and methods, as well as more data, are provided in (Cuppen et al. 2006d this proceedings).

It has been common practice (now illegal) to include preventive antibiotics in chicken feed in order to fight potential infection. This caused infections to be suppressed from the start, so keeping the chicken healthy they will properly develop and gain weight. This is usually estimate in what is called “feed conversion”, the number of kilograms of feed required for 1 kilogram of growth of the animal. To determine whether EMF could replace preventive antibiotics by providing enhanced immune response as a preventive measure, the feed uptake and growth were carefully measured per cage during the experiment, and corrected for the number of chickens actually present every day.

At the end of the growing cycle chickens were normally slaughtered and intestines evaluated for lesions as caused by the infection in a blind setup.

The results obtained are given in Tables 3 and 4.

Table 3: Feed conversion of broilers (kg feed consumed / kg weight increase).

	Negative control	Positive control	EMF no infection	EMF w infection

Feed conversion for the EMF treated groups was significantly improved in 4 out of 5 cases compared with non-treated groups. This result indicates that this EMF treatment has a similar effect as preventive antibiotics on feed conversion in the chickens. Of course this could be the result of an as yet unknown effect of EMF, but we consider it likely that the mechanism is through an enhanced immune competence of the chicken, and that therefore these results support our hypothesis.

Economically, these results are important as well, since 10 points feed conversion translate into a cost reduction of about 5 euro cents per chicken.

In experiment 3, we could also measure (blind) the damage of the infection in terms of lesions in the chicken intestines. The results are shown in Table 4.

The reductions in pathology after EMF treatment are significant in all measurements more than 5 days after infection showing less damage due to the disease and therefore indicating a better immune response with EMF treatment.

Discussion and conclusions

The in vitro and in vivo results clearly indicate that LF EMF treatment induces an enhanced immune response. It is not clear at present what the exact mechanism is of this EMF stimulation. In (Markov et al. 2006) we discussed that one of the key players of the immune system (T-lymphocytes) has a very specific response to EMF stimulation: react only when lymphocytes are activated. “Activation” means that the immune system gets the signal that something wrong is coming or going on. Then lymphocytes would be in high state of alert, ready to react. In Fig. 1, it is suggested that EMF stimulation and pathogens actually in combination trigger the immune system, giving it the signal that something “wrong” is indeed coming..

Moving from biology to fish and chicken farming, the results reported have extraordinary importance: by helping the immune system to handle infections in fish tanks, ponds or chicken barns, the LF EMF stimulation drastically reduces mortality and increases the efficiency of feed conversion. This is even more important since the preventive antibiotics are being banned for further application as feed supplement in the EU and other countries.

An additional advantage of the LF EMF stimulation reported on in this study is that it is achieved with a very low magnetic flux density which is a) economically and technically feasible in large areas and b) makes it unlikely that adverse effects would be initiated by this EMF stimulation.

All results above were obtained at levels less than 6.5 µT field strength (except one in vitro series at 1.5 mT) and in the one case tested, the effects were maintained even to a level of 0.006 µT. At these levels a direct effect on the pathogens is highly unlikely and the effect can only take place through resonance and the triggering of a system ready to react. A comparison might be made with a car stopping for a red light. No sufficient amount of energy was transferred to make any meaningful change in the process of the driving car. Nevertheless the signal was detected and a response generated that causes the car to stop. Likewise the minute signal required to generate the effects reported indicates that a physiological process was triggered that was waiting to go off.

In summary, our in vitro results indicate that the Immune signal indeed increases immune activity on cell level and that ROS production is increased causing oxygen stress at cell level. The in vivo experiments show a) reduced mortality and b) increased growth and reduced pathology after LF EMF treatment. The effects are strong, up to being actually relevant for animal management in farms. The effects measured support the hypothesis that LF EMF creates stress at cell level that can trigger an immune response that sustains itself after the immune system becomes active enough to attack a sufficient number of pathogens.

Abstract

The effects of pulsed electromagnetic fields (EMFs) were studied on processes and parameters of cell membrane of B16 metastatic murine melanoma cells and DC-3F transformed Chinese hamster lung fibroblasts. The fluid phase endocytosis were quantified on attached cultured cell under EMFs exposure.

The pulsed EMFs used were trains of low amplitude 900 MHz EMFs at a 217Hz envelope frequency, 580µs pulse duration, for times up to 30 minutes. Cells grown on Petri dishes were exposed at subconfluence using a wire-patch antenna or a TEM antenna. Endocytosis is critical for cellular functions like nutrition, signaling, transmembrane transport or surface area control. Fluid phase endocytosis is one main type of endocytosis corresponding to the liquid media engulfment in intracytoplasmic vesicles (endosomes) formed on the inner cell surface. Fluid phase endocytosis can be monitored by the Lucifer Yellow (LY, a fluorescent non diffusible dye) uptake and we previously showed that exposure of the cells to GSM microwaves significantly increases LY uptake in the absence of a temperature increase. The results here reported confirm and extend our previous observations. Indeed, we confirm that GSM microwaves increase LY uptake using another exposure system, a TEM irradiation antenna. Using known inhibitors of endocytotic pathways, we have identified, among the various cellular mechanisms resulting in external molecules engulfment, the mechanism that is actually affected by the exposure to the EMFs. Indeed, our data show that only the clathrin-dependent pathway is perturbed by the EMFs pulses while the potocytosis is not affected.

Introduction

Endocytosis is one of the basic cellular mechanisms participating to molecule exchange between the cell and its environment. Various ways of endocytosis mediate essential cell processes among which: extracellular molecules incorporation, membrane renewal and surface area control, antigen presentation, membrane receptor expression, etc. [1]. In the fluid phase endocytosis and the receptor mediated endocytosis, vesicles are constantly formed on the inner surface of the membrane and correspond to the absorption of extracellular medium into intracytoplasmic vesicles (endosomes). They detach in the cytoplasm and fuse with other internal cellular vesicles. The cytoplasmic surface of these vesicles is covered by a specialized protein, the clathrin. Pinocytosis is another related endocytosis process in which the vesicles also detach from the cell membrane even though they are not covered by the clathrin. Membrane area is restored by exocytosis, which corresponds to the fusion of internal vesicles to the plasma membrane. In the potocytosis, the vesicles (termed caveolae, and surrounded by a protein known as caveolin) formed at the inner cell surface do not detach but allow for active transport of molecules towards the cell inside. Apart from these general endocytotic pathways, specialized cells possess specialized endocytotic functions like the phagocytosis of the macrophages.

We previously showed that the incorporation of the Lucifer Yellow, a non permeant molecule that enter normal cells only by endocytosis, was increased under pulsed electromagnetic fields exposure (EMFs) using a standardised wire-patch antenna (Fig. 1). Here we confirm the increase in endocytosis using another exposure system, a TEM irradiation antenna. Moreover we have identified, among the various cellular mechanisms resulting in external molecules engulfment, the mechanism that was actually affected by the EMFs exposure.

Fig.3d. Modelling of TEM antenna with 35mm Petri dish with attached cells in culture to be exposed to GSM-EMFs.

Cells

F10 or F1 metastatic B16 murine melanoma cells and DC-3F transformed Chinese hamster lung fibroblasts were used. They were cultured at 37°C, 5% CO₂, in Eagle MEM (Gibco) supplemented with 10% foetal calf serum (Life Technologies), 100 units/ml of penicillin and 100 µg/ml of streptomycin (Gibco).

Exposure to EMFs

Two kinds of EMFs waves were used: (i) pulsed waves (GSM-EMF because they correspond to the EMFs delivered by the GSM mobile phones) consisting in 580µs-long square pulses delivered with a low frequency envelope at 217 Hz and with a high-frequency carrier sine wave at 900 MHz ; (ii) continuous wave (CW-EMF) consisting in a high-frequency sine wave at 900 MHz.

The signal generator RF S 900-60 (RFPA, Bordeaux, France) was delivering these two kinds of signals at adjustable powers ranging from 1 to 7 W (mean incident powers) for GSM-EMF and from 1 to 56 W for CW (mean or peak incident powers being identical for the CW-EMF).

EMFs in vitro exposure devices were a wire-patch or a TEM antennas.

Into the TEM antenna a single 35mm Petri dish with cells attached to was placed in the middle of the antenna.

Into the wire-patch antenna four Petri dishes were simultaneously exposed. Each 35mm Petri dish with the cultured cells was placed inside a 50mm Petri dish, used as a sample holder and both dishes were placed above another 50mm Petri dish. Both 50mm Petri dishes were containing water in order to preserve the same depth of the medium volume and the dielectric properties continuity. Therefore, a fair homogeneity of the EMF was achieved for the whole of the cells reducing the edge effects at the periphery of the 35mm dish [5].

For all experiments, cells were subjected to either EMFs exposure or sham exposure, under identical experimental conditions, in particular regarding to the location of the dishes in the wire-patch / TEM antennas and the location of the antennas in the incubator.

Media temperature was measured immediately before and after each exposure, using a digital thermometer and no significant rise in temperature was found at the powers used in the experiments, in agreement with the theoretical calculations.

Exposures were characterized by the **SAR** (Specific Absorption Rate) or power density absorbed by cell unit mass: $SAR = \sigma E^2 / \rho$, [SAR] = W/Kg with E = local electric field intensity, σ = electric conductivity and ρ = absorbing material density.

Endocytosis rate determination

The endocytosis rate was quantified by the accumulation of Lucifer Yellow (LY, Sigma), a non diffusible fluorescent dye. 24h before the experiment, the cells were seeded into 35mm Petri dishes in order to have a cell monolayer in exponential growth at the time of exposure. Cells were incubated for various time durations (ranging from 10 to 30 min) with 2 ml of culture medium containing 2 mM LY, in the presence or the absence of the applied EMFs. The incubations and EMFs exposures were done at 30°C. Immediately after the incubation, the cells were rapidly washed three times with 3 ml of NaCl 0.09%, trypsinized (Trypsin-EDTA 0.05%, Gibco), centrifuged (1000rpm, 10min, room temperature) and the cellular pellets resuspended in 1ml H₂O. Then, the cell suspension was sonicated 2x15s, at 100 W, on ice or chemically lysed. (Promega Lysis Reagent kit). The total fluorescence was measured using a spectrofluorometer (SFM 25, Kontron Instruments) at excitation and, respectively, emission wavelengths of 423 and 536 nm. The baseline was obtained for cells not exposed to the fluorescent dye. 20µl of cellular lysis was used for protein dosage (MicroBCA Protein Assay kit, Pierce).

For the experiments with endocytosis inhibitors, before the EMF exposure, the cells were incubated for 30 min at 37°C with Chlorpromazine Hydrochloride (Sigma) or Filipin III from *Streptomyces filipinensis* (Sigma). The two chemicals were also present into the media during the EMF exposure.

Viability of the cells incubated with 15µM Chlorpromazine or 1µg/ml Filipine III was 90 to 95%.of the viability of the controls (data not shown).

Results

The cells in the TEM antenna were exposed to SARs of 2.7 W/kg and 5 W/kg for 20 minutes. Indeed from previous work using the wire-patch antenna and the same cells, we knew that the exposed B16-F1 melanoma cells could display an increased dye uptake compared to the control cells after incubations times as short as 10min and we also knew that exposure to SARs between 0.6 and 1.3 W/kg had no significant effect on LY uptake while exposure to SARs between 2.6 and 4.5 W/kg significantly increased the LY uptake. Above an apparent threshold value under which no effect was detected, the increase of the fluorescent dye uptake was independent of the delivered GSM-EMF power, with a constant increase of approximately 1.5-fold with respect to control cells incubated under the same conditions but in the absence of the EMF exposure.

Cell viability after cells exposure to EMFs in the TEM antenna was similar to the viability in the controls (data not shown).

The results of cells exposure to GSM microwaves in the TEM antenna are reported in figure 4. Experiment was repeated 8 times, including each time an exposed and an unexposed Petri dish. As for the exposure in the wire-patch antenna, an statistically significant increase in the LY uptake was detected when cells were exposed at 5 W/kg ($p < 0.05$, paired t-Student's test). No significant increase was detected at 2.7 W/kg, a SAR value close to the threshold in the wire-patch antenna exposure system. These results confirm thus our previous observations.

Fig.4. Increase of LY uptake by B16F10 cells after 20min of incubation at 30°C, caused by GSM-EMFs exposure to various SAR (2.7 and 5 W/kg) into the TEM antenna. 100% correspond to $(19.8 \pm 3.04) \times 10^6$ LY molecules by cell. Each value is the average of 8 samples \pm SD.

To determine whether the increased LY uptake is due to a increase in classical endocytosis (mediated by the clathrin coated vesicles) or by potocytosis (mediated by the caveolin coated vesicles), the cells were preincubated with drugs selectively inhibiting these two endocytotic pathways: We used chlorpromazine that is a known inhibitor of the clathrin-dependent pathway [3], and Filipin III that is a known inhibitor of the potocytosis, that is of the caveolae-dependent pathway [4]. Results are reported in figures 5 and 6. Exposures were performed in the wire-patch antenna exposure system because several Petri dishes can be simultaneously exposed and because our previous experience using this exposure system.

Figure 5 shows that chlorpromazine slightly decreased LY uptake in the control unexposed cells. More interesting, chlorpromazine completely blocked the increase in LY uptake provoked by the exposure of the cells to the GSM microwaves. This results that the LY uptake pathway stimulated by the GSM microwaves is a clathrin dependent pathway.

Fig.5. LY uptake by B16F10 cells after 20min of incubation at 30°C, in the presence or not of GSM-EMFs pulses and/or 15µM chlorpromazine (CPZ). GSM-EMFs exposure of 3.2W/kg SAR into the wire-patch antenna. Each value is the average of 8 samples \pm SD.

Figure 6 shows that an increased endocytosis rate under EMFs exposure was still detected in the filipin III-treated cells. Thus the inhibition of the caveolin dependent pathway does not prevent the stimulation of the LY uptake by the GSM microwaves, suggesting that only the clathrin-dependent pathway is perturbed by the EMFs pulses.

Fig.6. LY uptake by B16F10 cells after 20min of incubation at 30°C, in the presence or not of GSM-EMFs pulses and/or 1µg/ml filipin III. GSM-EMFs exposure of 3.2W/kg SAR into the wire-patch antenna. Each value is the average of 8 samples \pm SD.

Summary

The results here reported confirm and extend our previous observations [2]. Indeed, we confirm that GSM microwaves increase LY uptake using another exposure system, a TEM irradiation antenna. Results are similar to those obtained using the wire-patch antenna even though significant increase at a SAR of 2.6 W/kg was detected with the wire-patch antenna and no significant increase was detected at a SAR of 2.7 W/kg with the TEM antenna. Indeed, these SAR values result mainly from models of energy deposition in the two exposure systems, approximately validated by measurements of temperature increase. Precision of both the models and of the measurements does not allow precise comparisons between the two exposure systems. At a SAR of 5 W/kg with the TEM antenna there is a statistically significant increase in the LY uptake. In the experiments here reported, the LY uptake increase in the cells exposed to the GSM microwaves was lower than 1.5 times the uptake in the control cells but this increase was still statistically significant.

The effects of the GSM microwaves on the endocytosis (LY uptake) are also confirmed by the effects of the two inhibitors used. Indeed, one of the two molecules tested actually inhibited the increase in LY uptake, while the other not. This excludes a non-specific effect of the addition of a chemical in the incubation medium. Simultaneously, the inhibition provoked by a known inhibitor of one of the endocytosis pathways confirms our previous observations and conclusions, namely that the exposure of the cells to the GSM microwaves affects the endocytosis pathways.

Moreover we have identified, among the various cellular mechanisms resulting in external molecules engulfment, the mechanism that is actually affected by the exposure to the EMFs. Indeed, our data demonstrate that only the clathrin-dependent pathway is perturbed by the EMFs pulses. Thus the potocytosis is not affected, while the classical endocytosis is actually modified by the cell exposure to the GSM microwaves.

Abstract

This paper deals with application of Transverse ElectroMagnetic (TEM) cell as an exposure system in technical and biomedical studies. In many publications is described problem of influence of an object upon the electromagnetic field (EMF) distribution inside a exposure system while inverse effect - influence of exposure system on tested object is overlooked. The problem plays primary role if a correlation between investigations carried out in an enclosure (eg TEM cell) and that in the free space is looked for.

Introduction

TEM cell was proposed by Myron L. Crawford in 1970 [3] as a new way of establishing standard, uniform EMF in a shielded environment and until now it is one of the most frequently applied EMF standard and exposure system. TEM cell is based on the idea that a TEM wave propagates inside a transmission line. Inside can be immersed an object that susceptibility to the EMF is tested. It is used for probes' calibration, electromagnetic compatibility and biomedical investigations (Fig. 1). The reasons of such popularity of TEM cell are its advantages: quite homogeneous EMF distribution inside the cell, similar to plane wave, wide frequency range, field intensity independent from frequency, simple EMF intensity estimations, etc.

However, "in the pot of honey is a spoon of a ter". Even not to mention the mutual interactions between the cell and object tested in it, these are: nonideal EMF distribution, moreover disturbed by the object, limited volume of the cell and the volume decrease with frequency increase, problems with larger objects testing in wide frequency range, etc. The former are discussed then while the latter are illustrated bellow. A concept of the homogeneity improvement by the way of covering the cell walls with a dielectric material is shown in Fig. 2. An approach to the frequency range widening is presented in Fig. 3. The slots limit tangential currents and, as a result, higher modes in the cell.

Fig. 1. A different way of using TEM cell.

Fig. 2. Dielectric sheets in a cell.

Fig. 3. A center conductor of a TEM cell.

What are the feelings of an antenna inside a cell?

Before we start our considerations related to biomedical experiments we would like to remind a problem of antenna's calibration in the cell, it would illustrate the role of mirror reflections phenomenon and then our way to farther considerations.

The answer to the question in the title is: due to infinite large number of mirror reflections (Fig. 5) the single antenna feels as an element of antenna system. If consider a cell without side walls, as in Fig. 1, and take into account only two plates, as shown in Fig. 4, the input reactance of a short dipole antenna X_i is expressed by:

$$X_i = X_{11} - \Delta X = X_{11} - 2 \sum_{i=2}^{\infty} (-1)^{i-1} X_{1i} \quad (1)$$

where: X_{11} – input reactance of the antenna in free space, ΔX – input reactance change due to a mutual couplings, X_{1i} – mutual reactance of the antenna and its i -th mirror reflection.

Presence of the mirror reflections, and their result ΔX , leads to a calibration error δ in relation to the free space conditions, the error we'll formulate in the form:

$$\delta = \frac{\Delta X}{X_i}. \quad (2)$$

Fig. 4. Geometry of calibration.

Fig. 5. Mirror reflections caused by metal sheets.

The input reactance of the antenna as well as the mutual reactances of the antenna and its mirror reflections is a function of its slenderness ratio. The slenderness ratio is a function of the relation of the antenna's length ($2h$) to diameter of its arm ($2a$). Calculated runs of the error δ versus $b/2h$ for $h/a = 30, 300$ and 1000 are shown in Fig. 6 [9]. In the estimations the plates were assumed infinitely large and perfectly conducting. The case while $h/a=30$ was reestimated on analytical and numerical way [4]. Results are presented in Fig. 7.

Fig. 6. Error δ versus y/h as a function of slenderness

Fig. 7. Error δ versus y/h for $h/a=30$.

ratio.

The above considerations allow several conclusions:

- real error of calibration is remarkably limited by presence at the input of a probe a capacitive divider,
- the phenomenon is of deterministic character and appropriate correction factors may be used to eliminate the error discussed,
- if the phenomenon exists in the presented case of an antenna calibration, a similar phenomenon should exist while in the cell any other material medium is immersed,
- if in the case of antennas a correction factor may improve accuracy of calibration similar approach should exist in the case of the medium investigations in order to find a way to refer the exposure conditions (and results of measurements) in the cell to that in the free space.

Numerical methods in biomedical dosimetry

An estimation of EMF energy absorption in any case may be done on the ground of the Maxwell equations solution. Unfortunately, analytical solutions are known only for the simplest structures. Even above presented estimations of input impedance of a dipole antenna required an assumption of it's perfect conductivity and sinusoidal current distribution along the antenna. The assumption may be accepted only for very thin structures. What to say about biological media where not only shapes may be arbitrary ones but the electrical parameters of the media are different for different tissues, organs and even parameters of the same tissues may be different depending upon a history of their donator. These limitations have lead, not only at our field, to necessity to use substitutional methods, i.e.: numerical ones. Along with the computer technology development and computers availability more and more sophisticated numerical methods and models were worked out.

The above is well illustrated by development of models applied in numerical dosimetry. In Fig. 7 are presented different models of a mouse (Fig. 7a). The oldest ones are spheroidal (Fig. 7b) [11] and cube (Fig. 7c) models. Follows them (Fig. 7d) a block model, containing of several cages, that allows bit better representations of the mouse's shapes and different electrical parameters. Now the most sophisticated model allows almost ideal reflection of investigated animal.

Fig. 7. Models of a mouse: a) real object, b) spheroidal model, c) cube model, d) block model, e) voxel model.

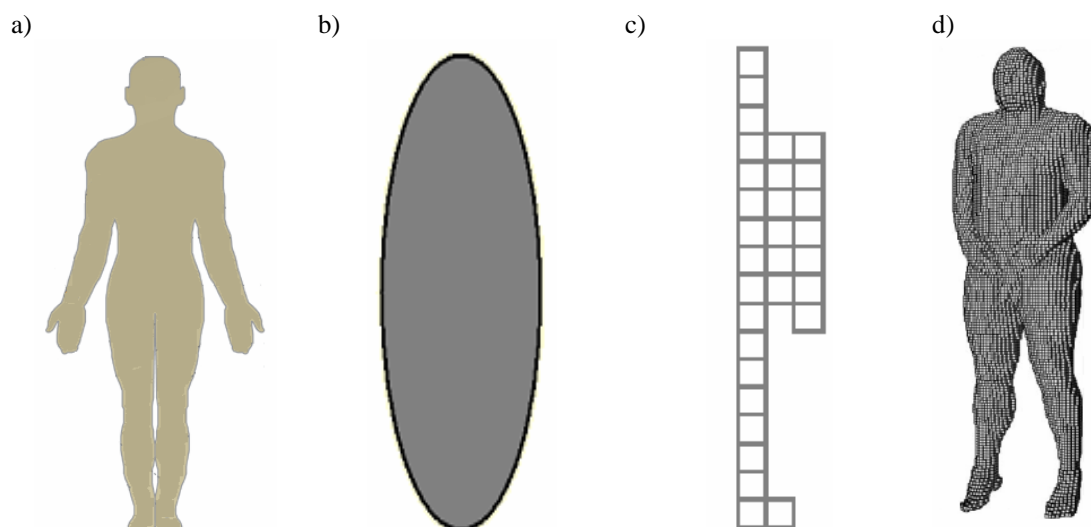

Fig. 8. Models of a man: a) real object, b) spheroidal model, c) block model, d) voxel model.

Similar development, as regards a model of the man, is presented in Fig. 8 [6] [7] [8] [10]. We may only remind here that homogeneous spheroidal and block models were applied in analytical studies, block model of a man was proposed by Guy and Johnson [10] and the most sophisticated "millimeter resolution" model of a man was developed by Gandhi [7].

It is evident that more sophisticated models require more sophisticated hard- and software. Both of them were not fully available to the authors. Thus, our estimations are limited to the use of rather simple codes (Maxwell SV [1], Fidelity [15]) and a possibility to use them in quite simple computers, as well as simple homogeneous or block models. With no regard to it our aim was not to strictly analyse presented phenomena, but only focus an attention of researchers upon the scale of the problem. From this point of view accepted tools and methods are fully correct and make it possible to present limitations in the exposure systems use and what is the most important, precautions in biomedical (and not only) experiments should be done.

In below presented estimations electrical parameters of animals and men were taken from [5] [6].

Biological object in a TEM cell

Studies of the effect discussed have been initiated by the authors [4]. The way of thinking was as follows: if a conducting medium close to an antenna is able to affect its input impedance, the same phenomenon should exist in the case of any arbitrary medium. A twofold question was here formulated: what does it mean "an input impedance of a mouse" and "a mutual impedance of the mouse and its mirror reflection", if an answer to the questions exists at all!

At the first step a cube model of a mouse immersed inside a TEM cell was studied. We assumed that the influence of the cell upon the object should be reflected by the power absorbed in it. The power is:

$$P_{abs} = 0.5\sigma \int_V |E|^2 dV, \quad (3)$$

where: P_{abs} – power absorbed by the object, σ – absorber conductivity, E – electric field intensity within the object, V - volume of the object.

Analysed homogeneous lossy model, in the form of a cube of side $h = 1.5$ cm, conductivity $\sigma = 1$ S/m and $\epsilon_r = 80$, was immersed between two parallel, perfectly conducting plates of sizes 20×20 cm and E-field was kept constant: $E = 1$ V/m. Results of estimations are shown in Fig. 9. If dimensions of tested object are quite small ($d \gg h$) P_{abs} approaches the value in the free space. However, while the object is large, as compare to d , the power may be remarkable different. The latter case has nothing common with results obtained in the free space. If distance between plates increases (ratio d/h increases) than power absorbed decreases and that means the committed error decreases.

Fig. 9. Absorbed power by examined cube.

Fig. 10. Comparison of results obtained with different numerical methods.

Similar results are obtained for more complicated model (Fig. 7d) of a mouse - block model (Fig. 11) that was made of 76 cube pieces of side 1 cm. The tissue values are the same as above.

Fig. 11. Results of absorbed power by block model of a mouse.

Fig. 12. Results of estimations of the E-field distribution: a) $f = 100$ MHz, b) $f = 1$ GHz.

In traditional approach, in biomedical investigations is assumed that the power absorbed within tested object is distributed homogeneously. It is not always acceptable. Lets analyse single object exposed in a TEM cell, in conditions while the proximity effects may be neglected. Results of estimations of the E-field distribution within the homogeneous cube, as described above, for two frequencies are shown in Fig. 12. Of course similar situations is for model of a man (Fig. 13). It is necessary to remind here that absorbed power, and the SAR, are proportional to E^2 , that makes that their distribution inside the model is more inhomogeneous as compare to E one, shown in the figures.

Fig. 13. Electric field inside model of a man.

Fig. 14. Location a mouse in relation to vectors [12].

Even in the free space conditions electric field distribution inside a model is non-homogeneous, as a result can be observed fact that each of the organs absorb different power. Results of SAR, for voxel model of a rat that orientation is defined by the incident field vectors (Fig. 14), are shown in Fig. 15. The model was processed in the far-field conditions at frequency 450 MHz.

Fig. 15. SAR calculated for different organs in a one-millimetre rat model.

Fig. 16. TEM cell with n examined objects.

A typical condition, in biomedical investigations, is simultaneous exposure in a cell more than one object, sometimes the objects occupy whole volume of the cell. Let's consider the cell while exposed several objects in it, as shown in Fig. 16. In standard approach the power absorbed in the cell (P_{abs}) is calculated as difference of the input and the output power: P_{in} and P_{out} respectively:

$$P_{abs} = P_{in} - P_{out} \quad (4)$$

Then, the power absorbed by i -th animal is calculated dividing the above by number of objects (n):

$$P_i = \frac{P_{abs}}{n} \quad (5)$$

There is no proof that powers absorbed by animals are identical. A few simulations were done to illustrate the statement. Firstly we considered the case where two mice were placed inside a TEM cell (Fig. 17a). One of them is placed in the center of the exposure system and the other in the center between the first one and the wall of the system. Similarly to above estimations the mice are represented here by cubes ($5 \times 5 \times 5$ cm) that parameters are: $\sigma = 0.84$ and $\epsilon_r = 80$. E-field intensity is constant and equals 1 V/m. Results, presented in Fig. 17b, confirm our doubts and show a magnitude of exposure estimation error while formula (5) is in use, in the worst conditions the power absorbed by mouse 2 is twice as much as power absorbed by mouse 1.

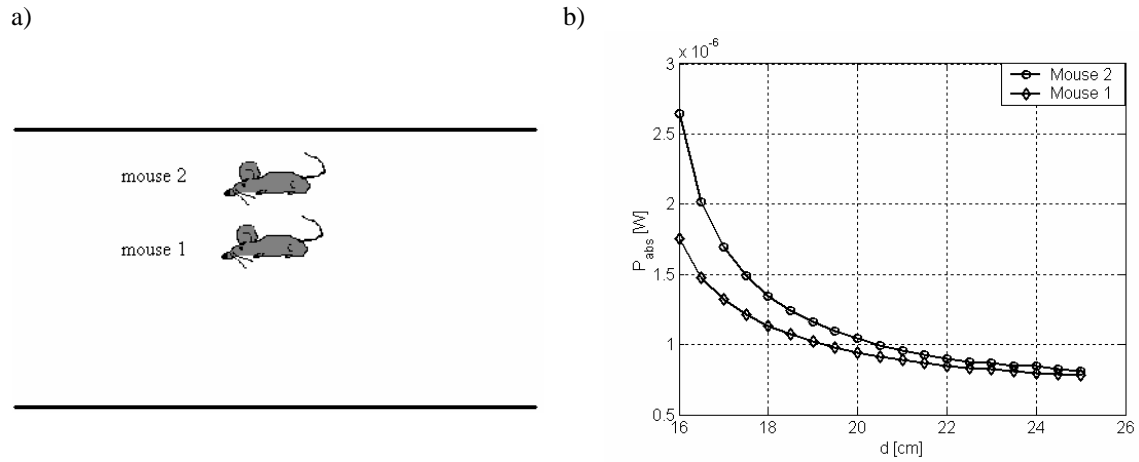

Fig. 17. Powers absorbed by two mice placed in TEM cell: a) model, b) results of calculations.

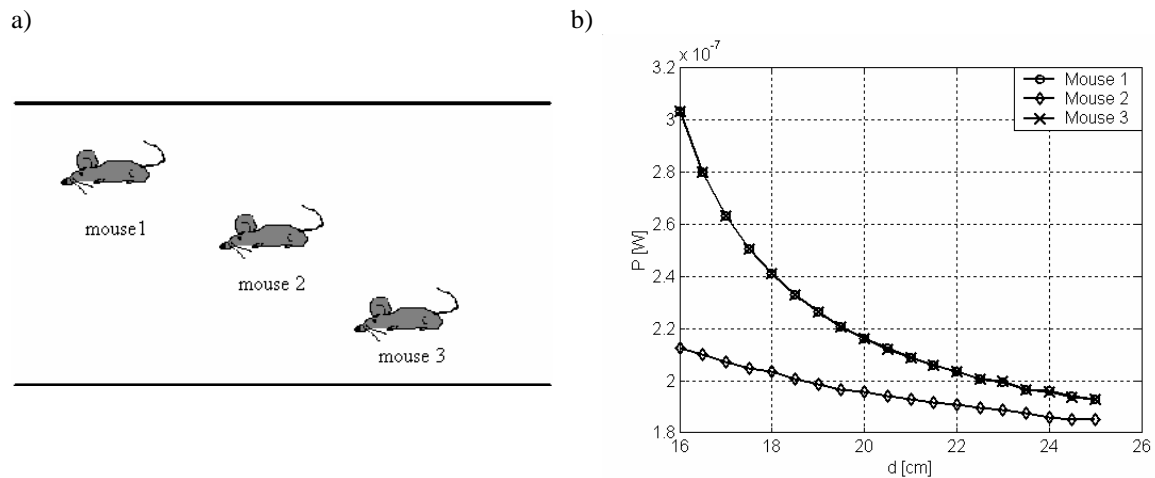

Fig. 18. Powers absorbed by three mice placed in TEM cell: a) model, b) results of calculations.

Similar effect exists in different space configuration of mice, like shown in Fig. 18. In this case the power absorbed by mouse 1 and 3 may be two times bigger than power absorbed by mouse 2. Again can be said that an assumption of identical power absorption in each examined object in discussed exposure system is not appropriate and it may lead to remarkable errors in experiments carried out in the conditions.

Conclusion

The paper discusses role of an affect, caused upon a tested object, by an exposure system due to existence of mirror reflections of the object in the walls of the system. The problem has never been considered before. The authors were inspired to start investigations in the field by estimations and experiments with the use of antennas in EMF measurements in close proximity of conducting objects or while the antennas were calibrated within a TEM cell or waveguide.

The question: what does it mean "input impedance of a mouse" remains unanswered, however, results of estimations, presented in the paper, show essential role of the phenomenon, especially in biomedical investigations while many animals are simultaneously exposed in an exposure system. Apart from different power absorbed by separate objects the absorbed power distribution within them is not homogeneous - especially at higher frequencies, even in the plane wave conditions.

Although the estimations were done for a TEM cell, their results are valid for any case while the discussed effect exists (waveguide, any conductivity media). Presented approach may allow to estimate a role of the phenomenon in any case and a possibility to refer results of exposure to the free space conditions.

Presented results lead to question:

- what is accuracy of biomedical investigations if do not take into account different exposure levels of different animals and even different their organs and tissues?
- what a way may be summarized very precise formulation of protection standards based upon such experiments?

Abstract

During the last decade the sources of radiofrequency electromagnetic (RF EM) radiation increased enormously both in residential and occupational environment. The study of the biological effects of RF EM radiation could contribute to better understanding of the possible health hazards. This study was designed to investigate the changes in hemolysis after *in vitro* exposure of human erythrocytes to GSM900 electromagnetic field (EMF).

Erythrocyte suspensions with two different cell concentrations (hematocrit 20% and 40 %) were exposed to EM radiation from GSM mobile phone (carrier frequency 902 MHz, 2 W output power in pulse) for 20 min. Alterations in haemolysis were registered 0, 10, 20, 30, 40, 50 and 60 min after the treatment. Hemolysis was determined by measuring the absorbance of hemoglobin at 413 nm in the supernatant obtained by centrifuging the suspensions. Hemolysis was expressed as a hemoglobin concentration.

Our data indicated statistically significant decrease in the hemoglobin level in irradiated suspensions. The GSM900 EMF exposure probably stabilized erythrocyte membrane and caused reduction in the hemolysis depending on the suspension water content (hematocrit) and on the time elapsed after irradiation.

Introduction

During the last decade the sources of radiofrequency electromagnetic (RF EM) radiation increased enormously both in residential and occupational environment. More and more people are exposed to EM radiation not only at work, but also at home. Particularly digital GSM (Global System Mobile) phones are biologically active, especially those with short, helical antennae [19]. To explore if the influence of mobile telephone is really hazardous for the human health, it is necessary to elucidate interaction mechanisms of electromagnetic field (EMF) with biological systems.

The study of the biological effects of RF EM radiation could contribute to better understanding of the possible health hazards. Research on the potential influence of EMF on living organisms and humans is performed at all different organization levels of organisms: from population studies via studies of individuals (humans and animals), cells and tissues (of humans, animals and plants; of unicellular organisms and bacteria) to the lowest, molecular level. Interaction mechanisms of low level EMF with biological systems are not clearly identified. Identifying them could help to find potential field targets in living material.

Reports from *in vitro* research indicate that low level high frequency fields may alter membrane structural and functional properties that trigger cellular responses. It was hypothesized that the cell membrane may be susceptible to low level high frequency fields, especially when these fields are amplitude modulated at extremely low frequencies [20]. There are abundant data on the effects of weak physical signals on cell functional activity. However cell targets for these signals are not established yet. Since water is the main component of biological systems and all metabolic processes take place in aqueous medium it was supposed that the minor changes in the physico-chemical properties of water could significantly modify cell functional activity. The data about the effect of EMF on water specific electrical conductivity and wheat sprouting serve as an additional evidence for the hypothesis according to which the EMF-induced water structure changing is an important pathway through which the biological effect of EMF is realized [6].

Evidences for directly non-thermal interaction with living systems are obtained after investigation of the RF EMF effects on the membrane permeability [2, 15]. These effects have not been explained by integral heating of the samples. Some other mechanisms such as formation of local temperature gradients in membrane-water interface or existence of hot spots in the system should be considered [11]. Changes in the ion transport and in the osmotic fragility are considered as an indicator for alterations in the erythrocyte membrane [1, 13]. Structural alterations were found out under the action of microwaves in membranes of granulocytes [22], erythrocytes [8],

melanoma cells (B-16 melanoma) [17]. Investigations of influence of EMF on the cation transport, membrane structure and fluidity show direct interactions of the field with specific membrane macromolecules or macromolecule complexes, which very often lead to global changes in the membrane properties. Considering the frequency dependence of the effects, different models for interaction of high frequency EMF energy and membrane components were submitted. The model about absorption of EM energy from water, bounded to biomolecules, is most likely [4, 14].

Microwaves could initiate chemically important events, i.e. configurational changes, e.g. multiple transitions between closely spaced vibratory states at successively higher energy levels. In the 10^8 – 10^{11} -Hz range, mono-water rotation occurs. Water-lattice vibrations (quasi-rotational or vibratory motions) may be important in the labialization of the primary and secondary structure of the biopolymers in the frequency range of 10^{11} – 10^{14} Hz. Other researchers believe bound water has a principal dispersion region in the range of 3×10^8 – 2×10^9 Hz [16].

The cell membrane, nervous cells and DNA molecules are considered in literature as most probably acceptors of microwave (MW) radiation. Cell activity and viability depend on the state of the cell membrane. Because of its unique bioelectrochemical properties the cell membrane is considered as primary acceptor of microwave radiation. A number of studies of EMF bioeffects have been performed on native and model membranes and substantial changes in membrane dielectric properties and membrane transport were reported.

Erythrocyte membrane is often used as a model membrane in investigating the structure and the functions of the biological membranes as well as in studying the influence of different physical and chemical factors on the membranes.

This study was designed to estimate the effects of GSM900 EMF *in vitro* exposure of human erythrocytes on hemoglobin release, their dependence on the suspension water content and on the time elapsed after irradiation.

Materials and methods

Erythrocyte concentrates were obtained from the National Center of Hematology and Transfusiology. Red blood cells were washed three times in 0.155 M NaCl ($2000 \times g$ for 10 min). After the last centrifugation suspensions were diluted to final cell concentration – hematocrit 20% or 40%.

The exposure was performed by GSM mobile phone type NSM-3, which was connected to a personal computer through an interface cable. The mobile phone was programmed via special software to emit carrier frequency 902 MHz (60th uplink channel of GSM900). The signal included standard GSM modulation. GSM signal was pulsed. The duration of the pulses was 577 μ s that corresponded to one time slot of TDMA frame. The TDMA frame in GSM systems has a duration 4.615 milliseconds (Fig. 1). Discontinuous transmission mode (DTX) was off during all exposures. Mobile phone pulse output power was 2 W.

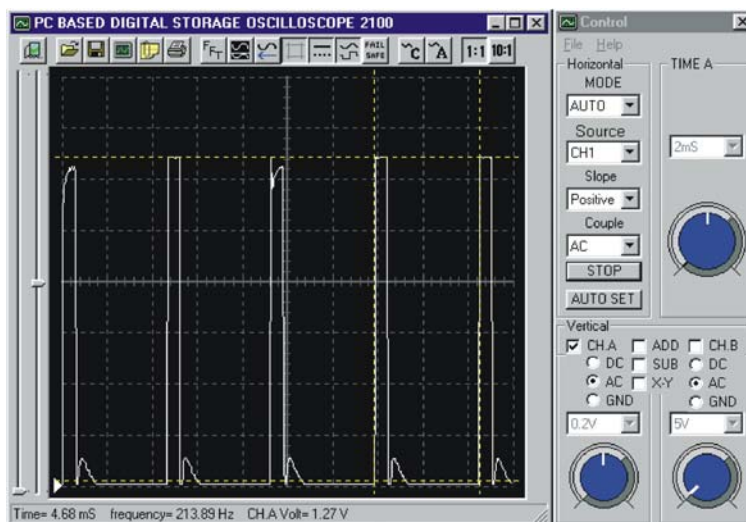

Figure 1. The emitted GSM signal, measured into mobile phone control circuit of the power amplifier.

Two milliliters of erythrocyte suspensions with different water content (hematocrit 20% or 40%) were transferred into two petri dishes (3 mm depth). One of them were control, another were exposed at 2 cm distance from the side of the mobile phone helical antenna. The exposure was 20 minutes. For eliminating of the influence of operator's hand on exposure conditions mobile phone was raised from the floor of 1 meter of the set up. The mobile phone and exposed erythrocyte suspensions were placed in the free space.

Alterations in hemolysis were registered 0, 10, 20, 30, 40, 50 and 60 min after the treatment. At given time intervals, 80 μ l of the suspensions (control and irradiated) were transferred to 1.3 ml 0.155 M NaCl in Eppendorf

ALTERATIONS IN HEMOLYSIS AFTER *IN VITRO* EXPOSURE OF HUMAN ERYTHROCYTES TO GSM900 ELECTROMAGNETIC FIELD

tubes and centrifuged at 10000rpm for 10s in a centrifuge MLW TH21. Hemolysis was determined by measuring the absorbance of hemoglobin in the supernatant at 413 nm. Hemolysis was expressed as a hemoglobin concentration (μM), calculated as follows:

$$C = E V_2 / \varepsilon l V_1$$

where: C – hemoglobin concentration; E – absorbance of the supernatant at 413 nm; ε – molar extinction coefficient, for hemoglobin at $\lambda = 413 \text{ nm}$ $\varepsilon = 120000 \text{ M}^{-1} \text{ cm}^{-1}$; l – length of the optical way (1 cm), V_1 – volume of added erythrocytes, V_2 – final volume.

The presented data are average and standard deviations of 8 measurement of the released hemoglobin quantity for each term. The Student t -test was used to estimate the statistically significant differences between the experimental samples.

Results and discussion

During the study of hemolysis in the process of blood aging we observed an increase of the quantity of the released hemoglobin with the increase of the time of blood storage. After the construction of the graphics *hemoglobin / days after blood taken* for control samples it was found that the values of the released hemoglobin between 2nd and 10th days were close (Fig. 2, 3). In the latest terms the quantity of the released hemoglobin was about 5 times more than at early terms. Because of the great differences in the quantity of the released hemoglobin, averaging of the results from spontaneous hemolysis before and after 10th day of blood storage would result in large standard deviations and would mask effects of the investigated factor. Experiments related to influence of different factors on the hemolysis should be made in the first 10 days of *in vitro* storage of the blood.

Figure 2. Quantity released hemoglobin from human erythrocytes in the process of *in vitro* blood aging (control, hematocrit 20%).

Figure 3. Quantity released hemoglobin from human erythrocytes in the process of *in vitro* blood aging (control, hematocrit 40%).

Represented data about the effects of GSM900 EMF (Figs 4, 5) are the averages and standard deviations of the values of released hemoglobin obtained in the first 10 days after the blood taken.

During the study of the hemolysis, we observed that the amount of the released hemoglobin increased with the time elapsed after the exposure to EMF both in the control and exposed erythrocytes. The differences between control and exposed cells are bigger at the beginning of the term of the blood storage at two studied hematocrits.

From the beginning of post exposure period to 60th min after irradiation the amount of released hemoglobin increased about two times in the erythrocyte suspensions with hematocrit 20%. There were no statistical significant alterations in irradiated erythrocytes immediately after termination of the exposure. Effects of EMF appeared 10 min after exposure and differences retains 30 min. There were no significant differences in the later terms (Fig. 4).

The *in vitro* exposure of erythrocyte suspensions with hematocrit 40% with GSM900 EMF for 20 min caused statistically significant decrease of the hemolysis (about 10-15%) compared to the control in all investigated terms (Fig. 5). Differences between control and exposed erythrocyte suspensions were more strongly expressed in suspensions with hematocrit 40%, which is close to physiological one (Table 1).

The obtained results showed that the EMF induces more significant changes in the suspensions with the lower water content (hematocrit 40%). These results contradict our previous results about the effects of 24 GHz MW *in vitro* exposure of human erythrocytes, where the most significant changes in erythrocyte electrophoretic mobility were observed in the suspensions with higher water content (hematocrit 20%) [12]. It is probably because the water content is of no importance in the realization of the effects of EMF on living organisms at this lower frequency (902 MHz). The decrease of the hemolysis is probably due to some stabilization of erythrocyte membrane after the irradiation with GSM900 EMF as a result of the field influence.

Figure 4. Quantity released hemoglobin from human erythrocytes after 20 min *in vitro* exposure to GSM900 EMF of the suspensions with hematocrit 20%.

Figure 5. Quantity released hemoglobin from human erythrocytes after 20 min *in vitro* exposure to GSM900 EMF of the suspensions with hematocrit 40%.

ALTERATIONS IN HEMOLYSIS AFTER *IN VITRO* EXPOSURE OF HUMAN ERYTHROCYTES TO GSM900 ELECTROMAGNETIC FIELD

Table 1. Rated decrease of the spontaneous hemolysis (compared to the control) and statistical significance of the differences between control and exposed to GSM900 EMF erythrocyte suspensions with hematocrit 20% and 40%.

Time after exposure, min	Hemolysis decrease compared to the control, %		Statistical significance (p)	
	Hematocrit 20%	Hematocrit 40%	Hematocrit 20%	Hematocrit 40%
0	4	15	-	0.99
10	10	13	0.98	0.99
20	11	14	0.99	0.99
30	8	14	0.95	0.999
40	10	11	-	0.99
50	3	12	-	0.999
60	3	11	-	0.999

These results are in consent with some authors. Microwave *in vitro* exposure (2.45 GHz, pulsed, power flux density: 5 mW/cm², exposure duration: 20 min, SAR: 400 μ W/g) significantly decreased spontaneous hemolysis of human erythrocytes at 42°C, but had no effect at 37°C or 48°C [9]. Some authors find no effects of high frequency EMF on hemolysis. Heating erythrocytes to 43°C for 10 min with microwaves (2.45 GHz, CW, exposure duration: 15 min, SAR: 91 mW/g) or hot air did not significantly increase hemolysis, compared with hemolysis at 4°C. Hemolysis of cells coated with concanavalin A-luminol-bovine serum albumin and heated to 43°C for 10 min by use of microwaves or hot air was significantly greater than that of controls at 4°C [10]. Possible nonthermal effects of 434 MHz microwave radiation (CW, exposure duration: 6 h, electric field strength: 15 V/cm, power flux density: 100 – 600 mW/cm², time of investigation: after exposure) on human blood should be investigated *in vitro* [5]. Plasma levels of hemoglobin and sodium and potassium ions serve as an indicator of haemolysis, caused by an increased membrane fragility. Indicated by the measurements no increased membrane fragility was observed, which could be clearly assigned to nonthermal effects.

Our results contradict the results of another authors, who state that exposure to high frequency EMF increases hemolysis. Cleary et al. investigated the effects of RF irradiation (10, 50, and 100 MHz, CW, exposure duration: 2 h, electric field strength: 1; 4,5; 9 V/cm) on cation permeability and hemolysis of rabbit erythrocytes *in vitro*. Potassium and sodium release were not altered by exposure. Hemoglobin release as an indicator for hemolysis was statistically significant increased at 50 and 100 MHz at field strength of 9 V/cm. The mechanism of the observed hemolytic effect is unknown [3]. Low intensity radiation from mobile phones leads to release of hemoglobin from red blood cells and accumulation of the hemoglobin in the body could result in heart diseases or kidney stones [7]. It was found that 2.45 GHz irradiation induces a significant hemoglobin loss due to transient permeabilisation of irradiated erythrocytes rather than to their lysis [18]. The microwave induced hemoglobin loss by irradiated erythrocytes is up to 80% of the spontaneous hemoglobin loss by the controls. The rate of the increase of hemoglobin loss with increasing power density was found to be highly dependent on the initial level of spontaneous hemolysis. It seems that the membrane is as more sensitive to the radiation power as it was leaker at the start. Kinetics of hemolysis degree at three different power densities was studied. At low power densities (0.8 and 1.36 mW/cm²) there is a quasi-linear increase of hemolysis degree with time of irradiation. At higher density (5 mW/cm²) this tendency seems to reverse after first 10 hours of irradiation. The only reasonable explanation for this seems to be that the spontaneous hemoglobin loss of controls increases faster than that of the exposed samples. It appears like long-term irradiation would exert a protective action against spontaneous hemolysis caused by cells ageing. This observation is paralleled by the results of kinetic measurements of the osmotic resistance of irradiated erythrocytes, which show a progressive increase of the osmotic resistance with time of irradiation at exposures to 5 mW/cm². Sajin et al. studied the effects of long-term exposure of human blood to 2.45 GHz irradiation at athermal power densities (CW, exposure duration: 60 h (84 h kinetic measurements), power flux density: 10 mW/cm², max value (50 W/m², 25 W/m², 10 W/m², 5 W/m², 2.5 W/m², 1 W/m², 0.5 W/m², 0.25 W/m²)) [21]. A significant increase of the hemoglobin loss by irradiated erythrocytes as well as a strong dependence of the rate of the increase of hemoglobin loss on the initial level of spontaneous hemolysis were revealed. It was found that at low power densities, the hemolysis degree increases quasi-linearly with the exposure time, while at higher density (5 mW/cm²), this tendency is reversed after first 10 h of irradiation. Long-term irradiation seems to exert a protective effect against spontaneous hemolysis caused by blood ageing. The osmotic fragility test performed on samples exposed to 5 mW/cm² at different

irradiation times showed that the osmotic resistance increased in time, reaching a maximum at the end of irradiation (60 h), while the osmotic resistance of the controls was constant.

The data about the effects of EMF on hemolysis in available literature are contradictory. More research and additional methods are necessary to decide these contradictions and to explain the mechanisms of low level RF EMF interaction with erythrocyte membrane.

Summary

Our data indicate statistically significant decrease in the hemoglobin level in irradiated suspensions. The 900 MHz EMF exposure probably stabilized erythrocyte membrane and caused reduction in the hemolysis that depended on the suspension water content (hematocrit) and on the time elapsed after irradiation.

ANALYTICAL METHOD FOR HUMAN EXPOSURE ASSESSMENT TO SHORT RANGE DEVICES

DINA SIMUNIC AND DAMIR ZRNO

***UNIVERSITY OF ZAGREB, FACULTY OF ELECTRICAL ENGINEERING AND
COMPUTING, UNSKA 3, HR-10000 ZAGREB, CROATIA***

Abstract

Electromagnetic dosimetry and exposimetry quantify electromagnetic fields inside and outside of the biological material, i.e., human body, respectively. They are primarily used for evaluation of human exposures due to various devices generating electromagnetic fields. The both: dosimetry and exposimetry have their bases in experimental and/or numerical methods. In this paper a proposed new formula for a SAR of short-range radio-frequency devices in multiple reflection environment has been developed. The involved scenario assumed semi-infinite plane with properties of homogeneous muscle. The shown results indicate that a reliable human exposure assessment in the indoor environment requires an application of deterministic numerical methods, capable of calculation of multiple reflection conditions, such as ray-tracing.

Introduction

Dosimetry and exposimetry of high-frequency fields have been investigated for a number of years in variously shaped object, like the prolate spheres [1] and spheres [2]. The dipole-type normal excitation has been studied in the semi-infinite slab [3], even under near-field conditions [4]. Human body in vicinity of wireless communications devices acts as a disturbing element of wireless communications systems performance [5]. On the other hand, biological effects of electromagnetic fields are being investigated also for a number of years [6]. Some numerical techniques, which are excellent tools for a calculation of deposited electromagnetic energy in the human body, like FDTD, are being extensively used throughout years [7]. Insofar, the attention has been mostly focused to cellular telephony. The constant development of new wireless technologies introduces presence of wireless technologies in the total human environment, which further complicates calculations of deposited electromagnetic energy. This paper presents an analytically developed SAR formula for multiple reflections conditions, natural to indoor environment.

Oblique incidence of plane wave

Let us suppose that tissue is a homogeneous material, so that it acts like a semi-infinite plane to the impinging

electromagnetic wave. The considered technology is in the ISM frequency range of short range devices (SRD), i.e., ISM part at 2.5 GHz. Analytical formulas have been derived for SAR of the SRD base stations. The SRD technology usually uses half-wave antennas, which allows us to conclude that all the calculations related to human exposure to SRD base stations have to be performed for far-field propagation conditions. For a plane wave travelling in air (Fig. 1), induced SAR at a planar interface air/tissue is defined by tissue mass density ρ , tissue conductivity σ , tissue impedance (Z_t) and power density in the tissue (S_t):

$$SAR = \frac{\sigma}{\rho} (S_t Z_t) \quad (1)$$

Fig. 1 shows a vertically polarized EM wave impinging obliquely the air/tissue interface. Air is characterized by μ_0, ϵ_0 ; tissue by $\mu_0, \epsilon_r, \sigma$.

Fig. 1 Oblique incidence of a vertically polarized wave

Transmitted power density in the tissue (S_t) is defined as a difference of the incident (S_{inc}) and reflected (S_{refl}) power density:

$$S_t = S_{inc} - S_{refl} \quad (2)$$

The transmitted power density, S_t , is at the air-tissue interface defined in terms of S_{inc} by a reflection coefficient Γ :

$$S_t = S_{inc} (1 - |\Gamma|^2) \quad (3)$$

SAR is defined at the air-tissue interface as:

$$SAR = \frac{\sigma}{\rho} S_{inc} Z_t (1 - |\Gamma|^2) \quad (4)$$

Tissue impedance, Z_t , is for the plane wave exposure defined by tissue conductivity, σ , tissue permittivity, ϵ_r , tissue permeability, μ_0 and angular frequency, ω :

$$Z_t = \sqrt{\frac{\mu_0}{\epsilon_r \epsilon_0 - j \frac{\sigma}{\omega}}} \quad (5)$$

Reflection coefficient depends on a wave polarization. For a vertically polarized wave impinging obliquely tissue, Γ_v , is defined by an incident angle (θ_1), free space permittivity ϵ_0 , tissue conductivity σ , tissue permittivity ϵ_r , and angular frequency, ω :

$$\Gamma_v = \frac{\sin \Theta_1 \left(\epsilon_r - j \frac{\sigma}{\omega \epsilon_0} \right) - \sqrt{\left(\epsilon_r - j \frac{\sigma}{\omega \epsilon_0} \right) - \cos^2 \Theta_1}}{\sin \Theta_1 \left(\epsilon_r - j \frac{\sigma}{\omega \epsilon_0} \right) + \sqrt{\left(\epsilon_r - j \frac{\sigma}{\omega \epsilon_0} \right) - \cos^2 \Theta_1}} \quad (6a)$$

Reflection coefficient for horizontal polarization Γ_h is slightly differently defined:

$$\Gamma_h = \frac{\sin \Theta_1 - \sqrt{\left(\epsilon_r - j \frac{\sigma}{\omega \epsilon_0} \right) - \cos^2 \Theta_1}}{\sin \Theta_1 + \sqrt{\left(\epsilon_r - j \frac{\sigma}{\omega \epsilon_0} \right) - \cos^2 \Theta_1}} \quad (6b)$$

The graphs for the both reflection coefficients, depending on the incident angle, are given in Fig. 2.

Fig. 2 Calculated reflection coefficient for vertically and horizontally polarized impinging wave

SAR in the tissue for a vertically polarized wave is defined as:

$$SAR_v = \frac{\sigma}{\rho} \left(S_{inc} \frac{\omega \mu_0}{\sqrt{\sigma^2 + (\omega \epsilon_r \epsilon_0)^2}} \left(1 - \frac{\left| \sin \Theta_1 \left(\epsilon_r - j \frac{\sigma}{\omega \epsilon_0} \right) - \sqrt{\left(\epsilon_r - j \frac{\sigma}{\omega \epsilon_0} \right) - \cos^2 \Theta_1} \right|^2}{\left| \sin \Theta_1 \left(\epsilon_r - j \frac{\sigma}{\omega \epsilon_0} \right) + \sqrt{\left(\epsilon_r - j \frac{\sigma}{\omega \epsilon_0} \right) - \cos^2 \Theta_1} \right|^2} \right) \right) \right) \quad (7a)$$

For a horizontally polarized wave SAR in the tissue is defined as:

$$SAR_h = \frac{\sigma}{\rho} \left(S_{inc} \frac{\omega \mu_0}{\sqrt{\sigma^2 + (\omega \epsilon_r \epsilon_0)^2}} \left(1 - \frac{\left| \sin \Theta_1 - \sqrt{\left(\epsilon_r - j \frac{\sigma}{\omega \epsilon_0} \right) - \cos^2 \Theta_1} \right|^2}{\left| \sin \Theta_1 + \sqrt{\left(\epsilon_r - j \frac{\sigma}{\omega \epsilon_0} \right) - \cos^2 \Theta_1} \right|^2} \right) \right) \right) \quad (7b)$$

Fig. 3 shows calculated surface SAR in dependence of impinging angle, θ_1 , with used electrical parameters in the 2.45 MHz frequency band for the homogeneous all-muscle model ($\epsilon_{2r} = 53.57$, $\sigma_2 = 1.81$ S/m, and $\rho = 1040$ kg/m³) for the both polarizations.

Fig. 3 Calculated ratio of surface SAR and incident power density in dependence of vertically and horizontally polarized obliquely impinging angle, θ_1 , at 2.45 GHz, with electrical properties of homogeneous all-muscle model

The results indicate that for a range of incident angles the ratio of surface SAR and incident power density depends highly on the polarization and on angle of incidence.

Multiple oblique incidence of plane waves

In the case of multiple reflections environment, where all reflected and transmitted components have a general arrangement and thus statistical phase difference, it is necessary to define a position of human body in the indoor space. Fig. 4 depicts a situation with only one barrier (e.g., a wall), which is placed at a distance ζ from the human being.

Even under these very especial and simplified circumstances (only one perfectly conducting wall), the analytical calculation of the reflected components of electric field is quite complex. The reflected field is calculated from a number of reflected components, i.e., the first reflection E_{1r} , the second reflection E_{2r} ,... the n -th reflection E_{nr} , by using incident field (E_0), reflection (Γ) and transmission coefficient (T), as given by Eqs. (8a-n).

$$E_{1r} = E_0 \Gamma e^{j\omega t} \quad (8a)$$

$$E_{2r} = E_0 T \Gamma^2 T^* e^{j(\omega t - \zeta)} \quad (8b)$$

$$E_{3r} = E_0 T \Gamma^3 T^* e^{j(\omega t - 2\zeta)} \quad (8c)$$

...

$$E_{nr} = E_0 T \Gamma^{(2n-3)} T^* e^{j(\omega t - (n-1)\zeta)} \quad (8n)$$

Fig. 4 Human body in a reflective environment with only one wall

Reflection and transmission coefficient depend on polarization and incidence angles. Reflection coefficient for vertically polarized field is given by:

$$\Gamma_{vm} = \Gamma_{lv} \frac{(\omega \epsilon_0 (\epsilon_r - \cos^2 \Theta_1) - j\sigma) (1 - \Gamma_{lv}^2 t_d^2 t_s) - t_d^2 t_s \sin^2 \Theta_1 (1 - \Gamma_{lv}^2)}{(\omega \epsilon_r \epsilon_0 - j\sigma) \cos^2 \Theta_1 (1 - \Gamma_{lv}^2 t_d^2 t_s)} \quad (9a)$$

Reflection coefficient for horizontally polarized field is defined as:

$$\Gamma_{hm} = \frac{\Gamma_{lh} (1 - t_d^2 t_s)}{1 - \Gamma_{lh}^2 t_d^2 t_s} \quad (9b)$$

Fig. 5 shows reflection coefficients for the multiple incidence of waves of the both polarizations.

Fig. 5 Calculated reflection coefficient for multiple incidence of vertically and horizontally polarized wave

Results of application of relation (4) for SAR with the reflection coefficient of multiple reflection of electromagnetic waves (9a) and (9b) are shown in Fig. 6.

Fig. 6 Calculated ratio of surface *SAR* and incident power density in dependence of incident angle θ_1 of vertically and horizontally polarized obliquely impinging wave at 2.45 GHz, with electrical properties of homogeneous all-muscle model, for multiple reflection

The results on Fig. 6. show that for a range of incident angles the surface *SAR* is equal to incident power density except for horizontal polarization for angles higher than approximately 75 degrees.

Fig. 7 Calculated ratio of surface *SAR* and incident power density in dependence of incident angle θ_1 of vertically (a) and horizontally (b) polarized obliquely impinging wave at 2.45 GHz, with electrical properties of homogeneous all-muscle model, for multiple reflection

Further inspection into the calculated results shows that there are differences in calculation of *SAR* for vertically polarized wave, following the reflection coefficient, where it can happen that for some angles (e.g., 82 degrees) the value of total *SAR* is up to 3.5 times higher than for the normal incidence.

These results show that for the relevant *SAR* calculation as many reflections as possible have to be taken into account. Also, it is of utmost importance to realize that calculation of normal incidence of electromagnetic fields does not indicate the so-called “worst-case” *SAR*.

Summary

The formula for *SAR* has been developed under the conditions of multiple reflections in a semi-infinite plane with electrical properties of homogeneous all-muscle model. The calculated results show that at certain incidence angles the *SAR* values for vertically polarized wave can be up to 3.5 times higher than for the normal incidence. Thus, it is of importance for *SAR* calculation in multiple reflective environment, such as indoor, to take into account as many reflected rays as possible. This can be performed by introducing numerical methods, such as ray-tracing [9],[10].

FULFILLING THE OCCUPATIONAL HEALTH TRAINING REQUIREMENTS OF EU DIRECTIVE 2004/40/EC

MICHAEL BANGAY

Radhaz Consulting Pty Ltd

Suite 5, 8 Clay Drive, Doncaster, Victoria 31 Australia

michael@radhaz.com.au

Abstract

This paper addresses the application of the European Union Directive 2004/40/EC in respect to worker information and training. The Directive has placed obligations on employers to protect their workers from risks to their health and safety arising from their workplace exposure to electromagnetic fields. Employers are required to meet particular health and safety requirements that include exposure assessment and worker training. This paper sets out an approach that achieves the employee training and information objectives described in Article 6 of Directive 2004/40/EC. An overview of training material provided in Australia by the author of this paper to meet similar requirements to Article 6 is presented.

Introduction

Governments around the world are reacting to the growing concerns over exposure to electromagnetic fields. While much of the concern has centred around the public's exposure to magnetic fields around high voltage power lines, mobile telephone emissions and radiated signals from telecommunications towers, there are new endeavours to address worker safety. Hazards associated with high-level exposure to radiofrequency (RF) fields have been well understood for many years. While the issue of injuries resulting from radiated low frequency fields like those around electrical power infrastructure is less clear, injuries caused by radiated RF fields and associated currents is quite clear and requires a response to protect both the employee and employer. The understanding about RF hazards and the way it can cause heating and burns extends back into the early days of radio use. Safety standards to guard against the heating effects of RF radiation have been in place for almost fifty years. The current preoccupation over possible athermal health effects alleged to be caused by exposure to levels of RF below the ICNIRP limits has possibly come at the expense of a more appropriate response to known RF hazards that need to be controlled.

During the mid 1980's Australia's government owned national telecommunications company faced a major occupational health and safety crisis with maintenance and installation staff refusing to climb masts/towers for fear that they may be physically harmed by the RFR radiation. The company responded by initiating a well-resourced hazard management program that included a hazard assessment and staff training. The training program has been continually refined over the past 20 years to produce training that establishes safe working procedures for all RF workers. This paper provides an outline of the training program conducted by Radhaz Consulting Pty Ltd over the past eight years.

Employers have an obligation to carryout an assessment of RF exposure levels around devices that emit RF radiation to determine if there is a risk that must be managed. Generally, a potential hazard is defined as an exposure situation that allows a worker to be exposed to levels that are in excess of the exposure limit values described in the Annex of Directive 2004/40/EC which were obtained from the ICNIRP guidelines ICNIRP7/99. These values are described as the occupational exposure limits and do not apply to members of the public. It is assumed that exposed workers have an intelligent awareness of the hazard and have their exposure controlled as a consequence of good engineering design, safe work procedures and training.

The initial assessment of the hazard by the employer to determine compliance or otherwise forms the basis of the measures needed to control the hazard. Depending on the circumstances, the assessment may be either performed by calculation or by measurement. Measurement is generally preferred for

frequencies below 110 MHz due re-radiation situations and the need to determine touch or induced current levels. The hazard assessment will determine the critical issues of frequency, applicable limit units and exclusion distance boundaries. For this reason the assessment should be performed by organisations with proven competences with accreditation from a suitable body. The accreditation requirements should ensure that the procedures, tools, instrumentation and personnel are of a sufficient standard to make certain that the assessment is credible.

Once an employer has established the possibility of a hazard there is an “duty of care” or obligation to control the hazard and apply the hierarchy of control these are:

- Elimination
- Substitution
- Isolation
- Engineering controls
- Administrative procedures
- Protective clothing and equipment

Concurrent with of the control the hazard is the education of the employees so that when they work with potentially high levels of RF radiation they may intelligently apply safe work procedures. In summary, the training of workers should cover the following topics:

- The properties of radiofrequency radiation
- The biological effects
- The safety standards that provide protection
- Clear presentation of the areas of high exposure in the worker’s workplace
- Safe work procedures
- The characteristics of an RF source that effect exposure

Properties of Radiofrequency radiation

Most workers do not have an adequate understanding of the properties of RF radiation. It is neither practical nor necessary to give workers a comprehensive or scientific understanding of RF radiation. However, it is appropriate to describe the relevant properties that may cause health effects and remove the misunderstanding that can cause unnecessary worry and disruption to the workplace. Some of the fundamental properties that need to addressed are:

- RF radiation is part of the electromagnetic spectrum
- RF fields are energy waves composed of electric and magnetic fields that can be modulated
- The waves are described by their frequency/wavelength and intensity
- RF radiation is part of the non-ionising spectrum and not like the ionising part of the spectrum that includes x-rays, gamma rays and UV light
- RF radiation is not the same as power frequency magnetic fields
- Is more similar to IR light in that the main known effect is heating

Biological effects

The knowledge regarding the known short-term effects about RF radiation is well established. This knowledge should have a direct bearing on the work practices of employees who are exposed to it during the course of their employment. The WHO has identified three known effects where there is an extensive body of scientific evidence to support their existence. These effects are: tissue heating by various mechanisms, neuro-stimulatory and acoustic. When describing these effects it is important to point out the influence of frequency showing that the level of absorption and the effect are related to frequency.

The neuro-stimulatory effect that is caused by the induced RF currents in tissue stimulating the nerves and causing an involuntary reaction is limited to frequencies of about 100 kHz and is more related to those workers who work with induction heaters.

The acoustic effect is a particular phenomenon that manifests itself as a clicking or buzzing in then ears when the exposed person is subjected to high power pulsed microwave fields like those around radar antenna. While this is an established phenomenon, it is quite rare to encounter the exposure situation that generates this effect.

Of greater importance are the heating effects which can range from cataracts, burns and heat exhaustion. It is this particular effect where most importance should be directed as it is relevant to most

workers who are employed in the field of radio communications and broadcasting along with manufacturing industries that use RF welding and drying equipment. The more serious injuries that generally occur are a consequence of high limb or contact currents that cause burns or nerve damage. High currents are generally through physical contact with a reradiating metal objects or live conductors/antenna elements. There are many documented cases where RF welder operators have received bad burns that require medical involvement. Similarly, workers who work around high power MF, HF and VHF broadcast antennas have received bad burns though contacting live conductors and reradiating guy wires.

While the more serious injuries occur as a result of contact currents, whole body heating can occur as a result of being in a strong ambient field like that around a HF broadcast antenna. The heating effects will be felt as either a localised heating more commonly in the ankles and lower leg or as a core temperature rise in the body that if allowed to continue would result in heat exhaustion.

While many workers express the concern that RF exposure may lead to male fertility effects, eye damage and cancer induction, it is important that the training puts these concerns in their proper perspective and alleviate unnecessary worry. It would require extremely high levels of sustained exposure that is well above the ICNIRP limits to cause eye damage and short-term fertility effects. There is no substantiated scientific evidence that RF causes cancer.

An important part of training is to raise the issue of medical implants that may be either metal rods as in the case of bone breakages or active devices like pacemakers. In these circumstances workers are advised to speak with medical specialist before working in areas that have high fields. Similarly, the issue of pregnancy needs to be addressed. Some authorities consider the unborn child for purposes of the exposure limits to be a member of the general public that consequently requires the mother to restrict her exposure to the general public limits. Should this approach be taken it would be necessary for pregnant workers to notify their employer with the intention of ensuring that their work place exposure does not exceed the general public limits.

Safety standards

Article 6 of the EU Directive requires workers to be provided with information about “the values and concepts of the exposure limit values and action values”. This component of the training creates a potential challenge for workers in the various industries using RF radiation. Quite often workers do not have an educational background or familiarity with the units of measurement that would otherwise enable them to understand the measurement terms. While it is simple to present a table with exposure frequencies and related limit values it is necessary to provide an explanation for the concepts. The key points to present are:

- Exposure limit values which ICNIRP calls Basic Restrictions which relate to power density at the skin’s surface, energy and current densities in the body which are not easily measured. Although important at a theoretical level, exposure limit values need not be taught in much depth.
- Action values are described by ICNIRP as Reference Levels and are the units of measurement for the physical quantities of electric and magnetic field strength, equivalent plane wave power density, contact current and induced limb current. Measurement of these quantities will determine compliance with the limits. A clearer understanding of action values needs to be given to those workers participating in training.

A successful method used by the author when conveying the concepts of action values is to build on knowledge of common every-day experience. This method includes using the analogy of radiated heat from an electrical radiator and the use of a domestic microwave oven to heat food. This allows more complex and less familiar concepts to be built on the knowledge of familiar and readily understood experiences.

Clear presentation of exposure areas in the worker’s workplace

A further requirement of the Directive is that workers receive the results of the exposure assessment. This requirement logically seeks to provide the worker with an understanding of where the areas of non-compliant exposure occur so that they may avoid those areas. The adoption of a common reporting format of hazard zones greatly simplifies this aspect worker information. A common graphical presentation that is gaining worldwide acceptance and is standard practice in Australia is to show site/building plans marked with two colours. The colour yellow depicts areas where the exposure

levels exceed the time averaged ICNIRP general public limits but are less than the occupation exposure limits. The colour red on the drawing shows the areas where the time averaged exposure levels are in excess of the occupational exposure limits. The use of simplified colour coded scale drawings enables workers to understand the hazardous areas without having to interpret units of measurement. Employers who provide a graphical presentation of hazard areas will fulfil their requirement to assess/map exposure areas and also provide the necessary hazard assessment information to their workers.

Australia has developed a standard reporting format for identifying RF hazard zones around transmitting antennas. The assessment report is known as a radio communications site management book (RCSMB) and finds its major use with radio systems that enable calculation of the exposure levels based on antenna gain/aperture and input power. The RCSMB is also suitable for use where exposure levels are determined by measurement and its format allows its use for industrial applications of RF. The RCSMB is the one document that addresses all of RF safety issues related to a particular site. The RCSMB contains the following sections:

1. **Site Contact Details** - *who should be contacted when any information is required*
2. **Site RF EME Diagrams** – *plan and elevation drawings showing exclusion zones*
3. **Site Access Control** - *Access Control Procedure - RF Hazard Warning Signs Installed - Special Requirements / Local Rules*
4. **Equipment Installed at this Site** - *Summary of Physical Equipment Installed - Equipment List*
5. **Site Specific Documents** – *Photographs – additional measurements*
6. **Safe Work Procedure** – *The procedures that need to be followed to ensure a safe workplace*
7. **Additional Information Sources** – *generic RF hazard information – web based information etc*

Safe work procedures

Every worker whose duties require them to access areas of RF exposure that exceed the ICNIRP general public limits need to have a written set of understandable safe work procedures. The procedures can be generic and applicable for all RF workplaces. The procedures should include:

- Read the site safety documentation (RCSMB)
- All workers accessing the area must be trained
- All workers entering the area must be authorized
- Obey all warning signs
- Assume all RF sources/antennas are active
- Have transmitters/sources locked out/disconnected before working on them
- Do not pass in front of the radiating faces of antennas, always pass behind/below
- Use personal RF monitors (PPE) when working around transmitting antennas or unfamiliar antennas. Note: specific training is a prerequisite for correct use

The characteristics of an RF source that effect exposure

The majority of sites will not have sufficient documentation to identify the hazard zones and it will be up to the worker to conduct their job safety analysis (JSA). Training needs to provide a basic understanding of the properties and characteristics of RF transmitting sources/antennas. This will enable workers to enter a site and generally determine where potential hazard zones exist. An important part of this training is to educate workers about transmitting antennas. The training material on antennas should not be at an engineering level or involve complex mathematics. Rather, it should focus on the physical differences that allow antennas to be defined to be either omni directional or directional with the emphasis on where potential hazard zones exist. A brief introduction to the calculation of radiated power flux levels should be given with attention being given to the three variables in the equation. The variables of gain, power and distance from the source should be explained in sufficient detail to enable the worker to see how these variables may effect their exposure.

Summary

Training for workers who work around RF transmitting sources is essential for their safety. It is possible to pitch the training material at an educational level that captures the majority of workers. The use of graphical materials (power point slides) and analogies from every day life will help most workers meet the training objectives. Wherever possible, workers should be encouraged to discuss their experiences and draw on their knowledge during group discussions. The training should not be delivered as a lecture; preferably, the training should be presented as small group training.

The training can be delivered in less than one day (4 – 6 hr) and should be accompanied by a comprehensive set of training notes. The training objectives need to be clearly stated with a written assessment conducted at the conclusion of training. A certificate should be issued if the assessment indicates correct understanding of the material.

Where possible the material should be accredited by an external educational/advisory organisation. The person conducting the training should be able to demonstrate an in depth knowledge of the material and have obtained formal training qualifications.

TRANSPARENCY FORUM - A RISK COMMUNICATION PROJECT IN SWEDEN

L. Mjönes and Lena Hyrke

**Swedish Radiation Protection Authority
SE-171 16 Stockholm, Sweden**

Abstract

The roll-out of the third generation system for mobile telephony has been fast in Sweden. The decision to build the UMTS system, 3G, was taken in 1999. In spring 2006 the population coverage for the system was over 90 percent. The rapid launching has created concern and opposition among parts of the general population. During 2004 and 2005 the Swedish Radiation Protection Authority, SSI, has arranged the “Transparency Forum”, TF, a series of three open seminars regarding the 3G roll-out where all stakeholders were involved: authorities, industry and NGO:s, including interest groups. The basis for TF is a risk communication model (RISCOM) for delicate situations. A key element in TF is that all stakeholders are involved on equal terms in the planning and realization of the project. The three seminars covered: Roles and responsibilities of the different organisations, The scientific basis for risk assessment and Risk management and precautionary principles. An independent evaluation company evaluated the project. The conclusion was that TF had offered an arena for stakeholders to meet and that the dialogue had been valuable. The evaluators pointed out that it is the responsibility of SSI to carry on working in the transparent way opened up by the TF.

Recent Risk Communication Activities in Sweden

The Swedish Radiation Protection Authority, SSI, is the competent authority for radiation protection in Sweden, both for ionising and non-ionising radiation. During 2004 and 2005 SSI has made special efforts to inform and educate the public and the municipalities as well as arranging other kinds of dialogue-projects concerning mobile telephony and health.

In 2004 a series of six regional one-day training courses, “Mobile telephony and health”, was organised by SSI and the National Board of Health and Welfare. The training course was offered to all Swedish municipalities. Altogether more than 300 regional and municipal employees and politicians attended the courses. The response from the attendants has been very positive.

Early the same year SSI took the initiative to a network of experts on mobile telephony and health in the five Nordic countries: Denmark, Finland, Iceland, Norway and Sweden. The work in this group resulted in a common position paper “Mobile Telephony and Health” (1). In short the Nordic authorities pointed out that there is no scientific evidence for adverse health effects from mobile telecommunication systems, but that some scientific uncertainty and knowledge gaps could justify a precautionary attitude regarding the use of handsets for mobile telephony.

During 2004 and 2005 SSI, arranged the “Transparency Forum for mobile telephone systems”, TF, a series of three open seminars regarding the 3G roll-out where all stakeholders were involved: authorities, industry and NGO:s, including interest groups. The basis for TF was a risk communication model (RISCOM) for delicate situations. A key element in the RISCOM model is that all stakeholders are involved on equal terms in the planning and realization of the project. The three seminars in TF covered: Roles and responsibilities of the different organisations, The scientific basis for risk assessment and Risk management and precautionary principles.

This paper describes the Transparency Forum in more detail.

The process of defining the project

The roll-out of the third generation system for mobile telephony has been fast in Sweden. The decision to build the UMTS system was taken in 1999. The licences for the operators were distributed in 2000. In spring 2006 the population coverage for the system exceeded 90 percent in Sweden. The rapid launching has created considerable concern and opposition among certain parts of the general population. The media coverage of the

3G issue has been intensive. Interest groups have been active in the resistance towards the launching of the new system and sabotage against masts carrying UMTS base stations has occurred. Also, individuals that have reported a variety of health problems that they relate to exposure to electromagnetic fields have argued that the authorities have neglected their problems. The debate at the municipal level has been intensive, involving local civil servants as well as local politicians. The building of masts has been appealed in court etc. SSI and other central authorities, have received critical views concerning the authorities' role in the controversy on new mobile phone technologies. One reason for this is the perceived technocratic approach that is no longer accepted. The need for a dialogue was obvious.

The RISCOT model of transparency

For more than 15 years, SSI has been working with risk communication in the nuclear waste arena, trying to achieve a better dialogue between different stakeholders. Using this risk communication experience and methodology, SSI has been co-financier in the development of a communication model for dialogue in different areas of complex issues of society – RISCOT (from RISKCOMmunication). One suggestion of the RISCOT approach is to create an arena for dialogue and discussion for concerned parties (2,3,4).

Decisions on certain complex issues, for instance regarding nuclear waste management, involve both scientific/technical and value-laden parts. If this is evident, transparent, both to the public and the decision-makers the decisions taken will generally improve in quality. It is also important that all parties understand the roles and responsibilities of the different stakeholders.

According to the RISCOT model, appropriate procedures must be created in which the decision-makers and the public can validate claims of:

- Truth (technical-scientific issues: Is this true? Are we doing things right?)
- Legitimacy (normative issues: What is fair, acceptable, legitimate)
- Authenticity (trust, no hidden agendas, personal integrity and organisational identity)

These are the three corner-stones (often illustrated as a triangle) in the RISCOT concept, they are equally important and interconnected.

It is seldom possible for the public to understand the scientific and technical issues in detail, or for the different scientists and experts to understand the details of each other's disciplines. Therefore, appropriate decision processes must be created; allowing the public to judge whether they can trust different scientists and experts. The public, and other stakeholders, must have the opportunity to evaluate the trustworthiness and authenticity of all parties involved. An important and useful tool to evaluate Truth, Legitimacy and Authenticity is the concept of "stretching". Stretching usually means that critical questions are raised from different perspectives and answered. All involved parties must allow themselves to be stretched. Public participation is essential for transparency and a satisfactory public involvement is not possible without transparency. The media is also important in a transparent process. Experienced journalists are vital for stretching scientists, experts and authorities but must also allow themselves to be stretched.

The RISCOT concept has been successfully applied in the nuclear waste management discussions in Sweden.

Transparency Forum

During 2004 SSI initiated a dialogue project outline on the launching of the third generation of mobile telephony, the "Transparency Forum for mobile telephone systems". The aim of this project was to improve the dialogue and transparency in society regarding electromagnetic fields, focusing on new mobile telephone systems, and to increase the mutual understanding of different stakeholders' roles and value judgements, so that different discussions will be addressed in the right arenas (political, technical, municipal etc.).

All kinds of relevant stakeholders have taken part in the project; authorities, industry and NGO:s, including interest groups. All were given the opportunity to express their opinions and ideas since a key element in RISCOT is that all stakeholders are involved on equal terms in the planning and realization of the project.

The reference group

A reference group was created, with a broad representation of the relevant stakeholders. The reference group did, at a series of regular meetings, take decisions on defining the process, program, timetable, meeting places, etc. A requirement for the Transparency Forum concept was that the project was to be defined and decided by this reference group, and not by SSI alone. The RISCOT principles were used all the way as the structure for

dialogue. Swedish authorities financed the project and SSI was the project manager, also using consultant experts.

A number of preparatory meetings were held to define the need for a dialogue process, starting with representatives from two municipalities experiencing a debate concerning the implementation of new mobile phone technologies. The municipal interest was very high, leading to widened meetings with other stakeholders, also approving the initiative (other authorities, municipal representatives, industry, NGO:s etc.). Therefore, a reference group with a broad range of stakeholders was established to define the Transparency Forum project. A project outline was created, that has been updated and accepted by the reference group, along with a formal agreement specifying the conditions for participating.

Organisations represented in the reference group:

Authorities

Swedish Radiation Protection Authority
National Board of Health and Welfare
National Electrical Safety Board
Swedish Work Environment Authority
National Post and Telecom Agency
National Institute of Public Health
Swedish Emergency Management Agency
Stockholm County Council (Medical expertise)
Nacka and Södertälje municipalities

Industry

Ericsson
MTB (Organises manufacturers and dealers of mobile phones)
Tele2 (Network operator)
TeliaSonera (Network operator)
Vodafone (Network operator)

NGO's

TCO Development (Labelling of mobile phones and other electronic products)
Vågbrytaren, Swedish for Breakwater (Interest group fighting unhealthy electromagnetic radiation)
FEB, Swedish Association for the Electro hypersensitive

Three interactive seminars

During the project preparation it was decided that three seminars should be organised where it would be possible for all stakeholders to state their true opinions and be questioned on their views by all others. The reference group decided on the following themes for the three seminars:

Seminar 1 - The roles and arenas of the different stakeholders

This first seminar was held late in 2004 and about thirty people attended. The seminar gave a description of the historical evolution of the new mobile telephone systems, focusing on decisions in political, technical, and economical areas that have led to the present situation.

To create a dialogue people have to meet, and be given the opportunity to understand other stakeholders' roles and responsibilities. Several Swedish national authorities are more or less involved when it comes to the question of UMTS, and the roles and interactions of these are not always easily understood. Therefore, a description of the interaction between different stakeholders and arenas was designed. Representatives for the involved authorities, industrial companies and NGOs gave accounts of their different views on the mobile telephone issue. A Member of Parliament representing the Green party presented that party's view.

After the presentations a number of interesting questions that had appeared during the day were discussed in working groups. Some of the questions were.

- How can Society take better care of people who claim to be electro hypersensitive?
- How can the precautionary principle be applied to mobile telephony?
- Who has the responsibility for weighing risk against benefits of new techniques?

- How should anecdotic reports and personal experiences be taken into account in the risk estimation process?

The discussion in the groups were loud and vivid, but were held in a good mood.

Seminar 2 - The research basis for the risk estimation

The second seminar was held for two days early in 2005 and about sixty people attended. The scope of the seminar was to discuss the research in the area of radiofrequency electromagnetic fields and health as a basis for the risk estimation for mobile telephony.

Risk evaluation and judgment is not a strictly technical and scientific issue, values also plays a very important role. It is important to understand how we, as individuals, perceive risks and makes personal risk judgments. The second seminar was therefore planned with a broad framing where the themes of discussion were:

- Radiation – physical and biological facts and risk estimations for electromagnetic fields
- Risk estimation concerning mobile telephone systems
- Different methods for risk estimation
- The basis for SSI's risk estimation and regulations for electromagnetic fields
- The situation for individuals who find themselves hyper-sensitive to electromagnetic fields

Among the participating scientists were Anders Ahlbom and Maria Feychting from the Karolinska group, Lennart Hardell from Örebro University, Jacob Eberhardt from Lund University (the Salford-Persson group) and Igor Belyaev from Stockholm University. Lars-Erik Holm, director general of SSI presented the authority's risk estimation for exposure from mobile phones and from base stations. Representatives for the industry and the interest organisations presented their respective views on the risks. The discussions and stretching after the presentations were intensive and sometimes rather aggressive

Also at the second seminar discussions in working groups were an important part. The group discussions were held at the end of the first day. A specific scope this time was that the groups should present questions that could be used for the stretching the next day. Four groups were formed:

1. Research on health risks from base stations and antennas
2. Research on electrical hypersensitivity
3. Risk estimation procedures
4. Research, methodology and evaluation

The working groups were successful in formulating a number of relevant questions for the stretching.

Seminar 3 - Precautionary principles and exposure limits

The third and last seminar, also for two days, was held in spring 2005 and about a hundred people attended. The scope of this seminar was to discuss precautionary principles and exposure limits as applied to mobile telephony.

Precautionary principles are used in many different areas and there are many different interpretations on the practical use and consequences. The precautionary principles relate of course to the use of exposure limits for electromagnetic fields. Themes to discuss were:

- Legal aspects of exposure limits and the precautionary principle (EU and national legislation)
- Exposure limits for electromagnetic fields
- Different interpretations and practical implications

The seminar began with a very interesting presentation on the background and the legal aspects of the precautionary principle by Annika Nilsson, legal expert from Lund University. Maila Hietanen, vice chairman of ICNIRP (International Commission on Non-Ionizing Radiation Protection) presented ICNIRP's work and the 1998 guidelines. Igor Belyaev gave an account of the guidelines from RNCNIRP, the Russian commission on non-ionizing radiation protection. The proposal from the WHO EMF Project for a Precautionary Framework, was

also presented. The second day concluded with a panel discussion focussed on exposure limits and how to apply the precautionary principle.

At the beginning of the second day the Swedish minister of the environment, Lena Sommestad, gave the Government's view on precautionary principles and exposure limits applied to mobile telephony. Lars-Erik Holm gave an account of the scientific basis of SSI:s risk estimation and exposure limits. He also presented the role of SSI:s international expert group on electromagnetic fields (5). After that other central Swedish authorities involved in mobile telephony: the National Board of Health and Welfare, the National Electrical Safety Board and the Swedish Work Environment Authority gave their views on the risk estimation.

A representative from Stockholm municipality discussed the rights of those who claim to be electrically hypersensitive and the industry and the NGOs in turn presented their views on the risk estimation. The second day of the seminar concluded with a questioning of some of the speakers and a panel discussion.

The evaluation of the project

To investigate whether the aim of the project was fulfilled, an evaluation was made by an external company specialised in evaluations of different authorities dialogue projects. The evaluation method that was used included different kinds of interviews and telephone questionnaires. Special care was taken to make sure that as many of the project's participants as possible took part in the evaluation. It was also important for the credibility of the evaluation that personal opinions should be taken into consideration and analysed. A special focus was therefore put on subjective impressions of both the project's accomplishment as well as the effects of the project.

The evaluation clearly shows that the majority of the participants have the distinct opinion that the project has resulted in an improved dialogue of the UMTS issue. The project has contributed to that the stakeholders have been sitting at the same table actually meeting each other's different opinions and views in a way that not had occurred in Sweden prior this project. There have also been different forms of learning and a new forum for dialogue has been created. Due to the meeting between different stakeholders with different opinions and values there has been an increased understanding for other stakeholders' roles and values. The project did not have as an aim to reach consensus (6).

The final report

During the entire project the documentation of the process has been of the greatest importance. Some parts of the seminars have also been recorded to make sure that all aspects of the interesting discussions were not lost in mere notes. It was stated already in the beginning of the project that the documentation would result in a final report. The idea was that this report would try to capture the very essence of the Transparency Forum; the dialogue itself. The report is being written not only for the participants of the project but also for all those who did not have the opportunity to participate in the project, of for example geographic reasons. The report is expected to be released in the autumn of 2006.

How is the dialogue continued?

Originally there was an ambition to continue the dialogue of Transparency Forum in a more permanent way, as a regular part of the work of SSI and other stakeholders. But in December 2005 the project was concluded and the reference group resolved. The evaluation points out that it is important to continue the dialogue. The question is how. For this there are no readymade plans as of today, but SSI is determined to continue the work that has been started. SSI has the intention to summon the stakeholders regularly to discuss different aspects of electromagnetic fields and health in order to maintain the dialogue.

Abstract

The aim of this study was to investigate the effects of a 0.5 T static magnetic field (SMF) of a MRI clinical unit on human CD4⁺ T cell lines in terms of cytokines content, expression of surface markers, cell proliferation. Cells were sorted by immunomagnetic beads from peripheral blood mononuclear cells (PBMC). Cells were cultured in complete medium and split into 2 groups of samples, one to be exposed and the other one as control. After 2 hrs of exposure to the SMF at 37°C, cells were stimulated or non stimulated with a mitogen, and incubated for 48 and 72 hrs. After 48 hrs of incubation it was observed in exposed CD4⁺ T cell lines: a decrease of IFN- γ production assayed by ELISA technique, a decrease of IFN- γ content, cell proliferation, expression of CD25 an activation surface marker- assayed by flow cytometry. After 72 hrs of incubation these effects were no statistically significant. This observation indicates that magnetic fields could have temporarily biological effects on T lymphocytes and that lymphocytes represent a sensitive model for the studying and understanding of the effects of magnetic fields on the immune system.

Introduction

The influence of static magnetic field (SMF) on biological systems has been a topic of considerable interest for many years [1-2]. We have previously demonstrated that SMF can influence the release of cytokines and intracellular calcium by human CD4⁺ T cell lines [3-6]. Immune system cells represent a sensitive model for the study and understanding of immunophysiological effects of the SMF [7]. The aim of this study was to investigate the effects of a 0.5 T SMF of a MRI clinical unit on human CD4⁺ T cell lines on cytokines content, expression of surface markers, cell proliferation.

Materials and methods

Peripheral blood mononuclear cells (PBMC) were isolated from heparinized blood by centrifugation on Ficoll-Hypaque (Pharmacia, Uppsala, Sweden). Cells were maintained in RPMI-1640 (Gibco, Grand Island, NY) supplemented with 10% heat-inactivated pooled human AB⁺ serum, 2mM L-glutamine, 20mM HEPES, 100 U/ml penicillin, 100 μ g/ml streptomycin, 5 x 10⁻⁵ M 2-mercaptoethanol and 150 IU/ ml rIL-2. CD4⁺ T lymphocytes were sorted by immunomagnetic beads, using an anti-CD4 specific monoclonal antibody (mAb) and CD4⁺ T cells were then expanded *in vitro* in IL-2/CM supplemented with a purified mitogen, phytohemagglutinin, PHA (Leucoagglutinin, 0,5 μ g/ml, Sigma, St. Louis, USA) and irradiated (30 Gy from a Caesium source) allogeneic feeder cells (PBL and Epstein Barr Virus-B cells at a ratio of 10/1). Cells were maintained for 2 weeks without restimulation prior to functional analysis. Purity of the CD4⁺ T cells was assessed by two colours flow cytometry. PE-conjugated anti-CD3 mAb was used with FITC-conjugated anti-CD4 (mAb Becton Dickinson, San Jose, CA). The cells were analysed by FACScan flow cytometer (Becton Dickinson, Mountain View, CA). This T cells expansion procedure, using PHA and allogeneic stimulation, induces expansion of virtually all CD4⁺ T cells and does not introduce any bias in the T cell repertoire. Cell culture was split into two groups of samples, one to be exposed and the other one as control to be kept under isothermal conditions for the whole time of the experiment, before the exposure to the SMF. After 2 hrs of exposure to the SMF, cells were stimulated with PHA, employed at a 0.5 μ g/ml suboptimal concentration. After 48 hrs and 72 hrs of cell culture, CD4⁺ T cells were collected and incubated at 37°C for 48 hrs and 72 hrs. A superconducting MRI unit (Vectra, GE Medical Systems, Milwaukee, WI, USA) commonly employed for clinical examinations was the source of the 0.5 T SMF. A specific device for keeping the cell samples at 37° C was used; it was constituted by a thermostated water bath in which a plexiglass tube holder with the tubes

containing cell samples were placed before their introduction within the gantry of the MRI unit. The experiment was repeated twice in different days. Intracellular staining was used to determine the IFN- γ intracellular concentration at the single-cell level both on exposed and sham exposed cell samples, before and after exposure to the SMF. Staining for intracellular nuclear antigen was performed by incubation of fixed permeabilized cells with FITC-labelled anti-Ki67 antibody and/or with PE-labelled anti-CD25 antibody (Becton Dickinson). After two more washes in PBS 1% FCS, the cells were analysed by FACScan flow cytometer (Becton Dickinson). Viable lymphocytes were gated by forward and side scatter and analysis was performed on 100,000 acquired events for each sample. Cells were harvested and fixed with 4% (w/v) paraformaldehyde in PBS for 10 min at room temperature. Fixed cells were suspended and washed twice with permeabilization buffer containing 0.1% saponin (Sigma-Aldrich, Milano, Italy), 1% heat-inactivated FCS, and 0.1% NaN₃ in PBS. The permeabilized cells were then incubated in the presence of saponin with FITC-conjugated anti-IFN- γ , anti-Ki67 and anti-CD25 (Sigma-Aldrich, Milano, Italy) for 1 h at ice temperature. After two more washes in PBS 1% FCS, the cells were analysed by FACScan flow cytometer (Becton Dickinson, Mountain View, CA). Viable lymphocytes were gated by forward and side scatter and analysis was performed on 100,000 acquired events for each sample. The IFN- γ , CD25 expression and Ki67 concentration were monitored by single excitation flow-cytometer technique. The fluorescence was recorded at 490 nm excitation and 520 nm emission.

Results

In CD4⁺ T cell lines exposed for 2 hrs to a 0.5 T SMF, after 48 hrs of *in vitro* culture, there was a decreased IFN- γ intracellular content and expression of CD25 surface marker with respect to sham exposed cells, that was enhanced in cells stimulated with PHA (Tab. 1, 2). The exposure also caused a decrease of the rate of proliferation of CD4⁺ T cell lines in exposed cells with respect to sham exposed, stimulated and not stimulated with PHA, as demonstrated by typical FACS intracellular analysis of Ki67 expression (Fig. 1). After 72 hrs of exposure there were not significant differences of the above parameters analysed between the exposed and sham-exposed cells.

Discussion

In this study we investigated the bioeffects of the SMF on the intracellular content of IFN- γ , CD25 marker expression and cell proliferation, using an homogeneous cell population of human CD4⁺ T cell lines. IFN- γ cytokine is a highly versatile homodimeric protein that plays an essential role in cell mediated immune responses to viral and mycobacterial infections [8]. The IFN- γ gene is located on chromosome 12 and codes for a 17 kDa protein, which then undergoes posttranslational glycosylation converting the IFN- γ to a 20-25 kDa glycoprotein. IFN- γ is produced by NK cells, dendritic cells, cytotoxic T cells, Th0 cells and Th1 cells. IFN- γ directs several immunoregulatory mechanisms that enhance the cytokine's function and increases the production of MHC class I and II, which in turn increase the likelihood that the infected cell will be recognized as such. Moreover, FACS analysis for CD25 expression, which is expressed as an early membrane marker of T cell activation, in exposed and sham exposed cells, treated and not treated with PHA, shows lower expression of CD25 marker surface in exposed cells. Furthermore, we evaluated the cells proliferation by the expression of Ki-67 protein. The Ki-67 protein is present during all active phases of the cell cycle (G1, S, G2 and mitosis), but is absent from resting cells (G0) and therefore it is an excellent marker for determining the so-called growth fraction of a given population. Although the functional role of Ki-67 protein during cell proliferation is unknown, it is unquestionable that Ki-67 protein expression and cell proliferation are closely linked. During the interphase, this antigen can be exclusively detected within the nucleus, whereas in mitosis most of the protein is relocated to the surface of the chromosomes [9]. In this paper, after 48 hrs of *in vitro* culture, a significant decrease of intracellular content of IFN- γ , CD25 expression and cell proliferation was observed in CD4⁺ T cells exposed for 2 hrs to the 0.5 T SMF of a MRI clinical unit with respect to sham exposed cells, stimulated and not stimulated with PHA. However, after 72 hrs of exposure there were not significant differences of the above parameters analysed between the exposed and sham-exposed cells. These results indicate that CD4⁺ T cell lines are a target population of SMF, and that the inhibitory effect of the latter is reversible.

Abstract

The effect of electromagnetic field (1 kHz, square wave) on the growth and essential oils of sweet basil (*Ocimum basilicum*) was studied. The plants in vegetative growth phase were discontinuously exposed to the electromagnetic field for 6 days, each 5 hours. The results showed decrease of the growth of shoots of treated plants compared to the control group. The activity of polyphenol oxidase was increased by the treatment, whereas the amount of volatiles, in particular of methyl chavicol was decreased. It can be suggested from the results that electromagnetic field exposure of basil caused metabolism pathway shifted from producing essential oil to the synthesis of other metabolites.

Introduction

Interaction between cells and extraneously applied electromagnetic fields (EMFs) have been investigated over last years and many of them have focused on their influence on the growth of organism (Hirano et al., 1998; Davis 1996). However, investigations, dealing with effect of EMF on the performance are scarce and the possible mechanism of the effects of electromagnetic fields on the cells are yet to be elucidated (Panagopoulos et al. 2002).

According to a simple hypothesis an oscillating, external electric field, by exerting an oscillating force on the free ions on both sides of the cell membranes can give a false signal for gating channels that leads in turn to disordering the membrane and therefore the whole cell function (Panagopoulos et al. 2002). Any slight membrane structure disturbance could potentially lead to detectable physiological and biochemical effect. In plants it has been shown that exposure to EMF can alter the metabolism of certain amino acids e.g., asparagines, glutamine, alanine and GABA (Ben-Izak Monselise et al. 2003).

The present study the effect of EMF on the growth, the quality and the quantity of essential oils of sweet basil (*Ocimum basilicum*), a plant of high economic value was studied.

Seeds of sweet basil were cultivated in a soil containing sand-clay and humus (2:1) and grown at 27 ± 2 °C and 16 h photoperiodic with a photosynthetic photon flux of $58 \mu\text{mol m}^{-2} \text{s}^{-1}$ at the plant level. Micro- and micronutrients and physical parameters of the soil are shown in Table 1.

A locally designed electromagnetic wave generator capable to generate different wave shape including sinusoidal, triangular and quadratic, was used. This system could generate EMF in the range of 0.1HZ– 10 KHZ with a continuous fine control in stable conditions. It was consisted of two vertical coils each 28 turns of 0.3 mm copper wire rounded around a quadratic frame of 48×34 cm. One coil oriented in vertical plane (XOZ) with pointing vector in horizontal direction (anti parallel with the gravity) while the other coil oriented in horizontal plane (XOY) with pointing vector in vertical direction (perpendicular with the gravity). Impedance of each coil was 8 ohm. The maximum consuming power of the system was 9 watt controlled by a fine analog controller. The calibration of system was performed at three different frequency (50, 300 and 1000 HZ) in the center of the chamber. The consuming power was 8 watt at 1kHz in which the average electric and magnetic strength were $96/3 \pm 4.8$ (kV/m) and 984 ± 43 (mA/m), respectively. A digital thermal sensor was used to control the temperature inside the chamber during the exposure. While the sample were exposed to the defined EMF, the control samples were placed in the same conditions (i.e., the same temperature, humidity and light intensity), but far enough from the apparatus, being shielded from possible exposure. The plants in vegetative growth phase were discontinuously exposed to the aforesaid EMF for 6 days, each 5 hours. After the period of exposure, plants were gathered and kept at -80 °C until used for biochemical and analysis. The rate of growth as well as the ratio of fresh weight to dry weight of

EFFECT OF EMF ON ESSENTIAL OILS OF BASILE

the samples before and after the treatment were measured (Table 2). Statistical analysis was done by SPSS and t-test and the differences were considered significant at the level of $p \leq 0.05$.

Polyphenol oxidase (PPO) was extracted from homogenized cells in freshly prepared 100 mM Na-phosphate buffer (pH 6.8) followed by centrifugation at $15,000 \times g$ for 20 min (Kahn 1975). Aliquots of supernatant were added to 100 mM Na-phosphate buffer (pH 6.5) and freshly prepared 4-methylcatechol at a final concentration of 0.02 M. The increase in absorbance at 410 nm per min per mg protein content of the homogenate was the expression of Enzyme activity.

The essential oils were extracted from 50 g (dry weight) of shoot samples by steam-distillation for 3h using a Clevenger type apparatus and were analyzed by GC and GC-MS.

Analytical gas chromatography was carried out in a GC-9A (Shimadzu, Tokyo, Japan) equipped with a DB-5 fused silica column (30 m \times 0.25 mm, film thickness 0.25 μ m, J & W scientific corporation). Oven temperature was held at 60 °C for 5 minute and then programmed to 210 °C at a rate of 3 °C/min. Injector and detector (FID) temperature were 270 °C; helium was used as carrier gas with a linear velocity of 32 cm/s. Percentages were calculated by area normalization method without the use of response factor correction. The retention indices were calculated for all compounds using a homologous series of n-alkanes.

GC-MS analysis was carried out on a GC-MS system (Varian 3400, USA) equipped with a DB-5 fused silica column (30 m \times 0.25 mm, film thickness 0.25 μ m, J & W scientific corporation); Oven temperature program was 50 ° - 60 °C at a rate of 3 °C/min. Transfer line temperature 270 °C, carrier gas helium with a linear velocity of 31.5 cm/s, split ratio 1/60, ionizing energy 70 ev, scan time 1 sec, mass range 40-300 amu.

The constituents were identified by comparison of their mass spectra with those in a computer library (LIBR-TR and Wiley5 lib.) or with authentic compounds. The identifications were confirmed by comparison of their Retention indices in table 3, either with those of authentic compounds or with data in the literature.

The result showed that the growth of the plants treated with EMF was decreased compared to that of the control group, whereas the ratio of fresh weight to dry weight of increased with EMF-exposed plants were higher than those of the control ones (Table 2).

There activity of PPO of EMF-exposed plants was also significantly higher than that of the control plants (Fig.1).

In comparison to control plants, the amount of the total volatiles of EMF-exposed plants was reduced. The major components of the essential oils of both control and EMF-treated plants were methylchavicol, nerol and geraniol, however the amount of methylchavicol was significantly enhanced by exposing to EMF (Table 3).

EFFECT OF EMF ON ESSENTIAL OILS OF BASILE

Summary

The mechanism of the effect of EMF on plant metabolism is still unclear. However, it has been suggested that the production or enhancement of free radicals (Scott, 1993) and ferrous ions (Miyakoshi, 2005), ion change and mass resonance are involved in the adverse effects of EMF on the growth and metabolism of plants.

Decrease of growth can be resulted from damage DNA, proteins, cellular membranes and mutiple genes (Da Silva et al., 2000; Sahebjamie et al. 2006).

Polyphenol oxidase is responsible for tissue browning of raw fruits and vegetables (Mathew & Parpia 1971), which has been found in most higher plants. PPO is a bifunctional enzyme that hydroxylates monophenols to O-diphenols, the only specific reaction catalysed by this enzyme (cresolase or monophenolase) and also oxidizes self generated O-diphenols to the corresponding o-quinon (catecholase or diphenolase) (Gowda & Paul, 2002). Most phenolics that are oxidized by PPO, are intermediates or derivatives of the shikmate and phenyl propanoids pathway. In the present study the increase of the activity of PPO in EMF-exposed basils was not accompanied by an increased production of essential oils. From the results presented here it can be suggested that in EMF-treated plants the activity of PPO shifted from producing essential oil to the synthesis of other metabolites like quinines. Interestingly, despite to the reduction of the of total essential oil content in EMF-treated plants, the amount of methyl chavicol, a main medicinal volatile of basil increased by EMF. Taking all together, the results presented by this study suggest that EMF can be applied as a useful tool to manipulate the metabolism of medicinal plants in order to obtain more desired components.

Abstract

It is found that reasons for a poor replicability of the nonthermal bioeffects of electromagnetic fields of the extremely low frequency (50-60Hz) have the fundamental basis, revealed by the thermodynamic theory of systems under the Rayleigh-Jeans radiation. It is shown the difference between the Rayleigh-Jeans region and the Wien region of electromagnetic radiation from the viewpoint of energy conversion. The rules and conditions of the good replicability of medical and biological experimental results are formulated.

1. Introduction

The discussion of the electromagnetic fields of extremely low frequency (50-60 Hz) effects on health had began in 1979 with the report by Wertheimer and Leeper [1], who noted that the incidence of cancer was much more in children living in houses where electromagnetic fields exposure was presumed to be higher than usual. This report has given rise to important problem because the exposure of increasingly larger human populations to higher mean levels of extremely low frequency electromagnetic fields is an outcome of the electrification of residential and commercial buildings, particularly in the well-developed countries of the world. The intensity of these man-made fields is substantially more than the ambient nature electric and magnetic fields. Later many epidemiological studies have been published concerning the effects of electromagnetic fields on health, mainly on possible carcinogenic effects. One part reported presence of an association between field exposure and human cancer (leukemia), brain tumor and breast cancer [2,3], but the second part had not found this association. The experimental researches both in vitro and in vivo in this sphere were conflicting too. And may be, that the findings of effects absence are more frequent [4]. So great length of this discussion shows the complication and importance of the problem. Prof. R. Reiter called this situation the Cheshire cat phenomenon [5].

Similar situation was presented in [6] and is connected with bioeffects under microwave radiation. To be more specific, we can say with reasonable confidence that in the present-day a matter of microwave region is more dramatic, as the some scientists do not study the nonthermal bioeffects since they are sure that they do not exist, while the others (Russian) scientists cure many illnesses (cancer etc) on these effects basis.

This conflicting situation may be changed for the better, if the experimentalists use the advances in the nonequilibrium thermodynamics of systems under electromagnetic radiation [7]. This theory shows that the large field of phenomena which were before considered as independent ones, follows a general law of nonequilibrium thermodynamics. This law governs the phenomena of conversion of electromagnetic radiation energy into electrical work, chemical bonds energy and luminescence. It is valid for living and inorganic systems. The qualitative and quantitative validity of this theory was tested in solar cells and it allowed to calculate the dependence of entropy generation rate on absorbed power of radiation due to the irreversibility of a process. This theory is useful in understanding the various aspects of human vision, protozoa photomovement, photosynthesis of plants, nonthermal bioeffects of radiofrequency radiation and other processes. The aim of this paper is to show the reasons of the Cheshire cat phenomenon existence.

2. The thermodynamic law of the isothermal processes under electromagnetic radiation

As it is known [8], the efficiency η of the isothermal conversion of electromagnetic energy into Helmholtz free energy F in open thermodynamic systems is defined as

$$\eta = \Delta F / \Delta W_a \quad (1)$$

where ΔF is the change of the Helmholtz free energy of the products at the outlet from the system in relation to Helmholtz free energy of the reactants at the inlet of the open thermodynamic system and ΔW_a is the electromagnetic radiation energy, absorbed by the system. If $\Delta F > 0$, we have the endergonic process and if $\Delta F < 0$, we have the exergonic process.

In line with the first and second laws of nonequilibrium thermodynamics for the steady state of a system we have the relation [7]

$$\eta = 1 - T (\dot{S}_a + \dot{S}_i) / \dot{W}_a \quad (2)$$

where T is the temperature of the system, \dot{W}_a is the absorbed power, \dot{S}_a is the flux of entropy of electromagnetic radiation absorbed by the system, \dot{S}_i is the entropy generation rate as a result of the thermodynamic irreversibility of the process.

Usually in work concerning isothermal process, the thermodynamic method is used to analyse only the limiting efficiency η^* obtained from Eq. (2) under assumption of thermodynamic reversibility of the process, i.e. with the condition $\dot{S}_i = 0$ [9]. Then

$$\eta^* = 1 - T \dot{S}_a / \dot{W}_a \quad (3)$$

We can find η^* for nonequilibrium electromagnetic radiation with arbitrary spectral characteristics, using follow equations

$$\dot{W}_a = \int E_\nu d\nu \quad (4)$$

$$\dot{S}_a = 2\pi k c^{-2} \int \nu^2 [(1+\rho) \ln(1+\rho) - \rho \ln \rho] d\nu \quad (5)$$

$$\rho = c^2 E_\nu / 2\pi h \nu^3 \quad (6)$$

where k is the Boltzmann constant, h is the Planck constant, c is the speed of light, ν and E_ν are the frequency and the spectral density of absorbed radiation power respectively.

The analyse of Eq. (3) with Eqs. (4 – 6) shows that there are two regions of energy conversion, where the dependence of the η^* on absorbed power \dot{W}_a is quite different because of the ρ may be both more and less than unity [6, 10].

For the $\rho \gg 1$ we have

$$\dot{S}_a = 2\pi k c^{-2} \int (1 + \ln \rho) \nu^2 d\nu \quad (7)$$

and for $\rho \ll 1$

$$\dot{S}_a = 2\pi k c^{-2} \int \rho (1 - \ln \rho) v^2 dv \quad (8)$$

The region, which corresponds to the $\rho \ll 1$, is the Wien region and the other one, which corresponds to the $\rho \gg 1$, is the Rayleigh-Jeans region. These regions are known to experimentalists as the regions, where $h\nu \gg kT$ (the Wien region) and $h\nu \ll kT$ (the Rayleigh-Jeans region). It should be substituted the corresponding values in to Eq. (6) to be certain that is the case.

Fig. 1. Dependence of limit efficiency η^* on logarithm of absorbed power spectral density E_v for the Wien region (solid line) and for the Rayleigh-Jeans region (dotted line). E_v is measured in J/cm^2 .

The upper limit of the η^* is equal to 1 in both the Wien region and the Rayleigh-Jeans one, but the dependence η^* on absorbed power (or the spectral density E_v) is different. It is slow in the Wien region, where the limit efficiency and absorbed power \dot{W}_a (or E_v) have the logarithmic relationship. The dependence η^* on E_v in semilogarithmic coordinates is the straight line, and the interval of E_v , where the η^* takes the values from zero to unity, is very large (solid line in Fig. 1). In the Rayleigh-Jeans region the η^* dependence on the absorbed power \dot{W}_a (or E_v) is very strong until it flattens out on a plateau, where $\eta^* = 1$. The thermodynamic limit efficiency varies from 0 to 0.9 with a tenfold increase in E_v (dotted curve in Fig. 1). Both these curves have the point, where $\eta^* = 0$ and exergonic process is balanced out by endergonic one. The geometry place of these points is defined by [10]

$$c^2 E_v^0 = 2\pi k T v^2 [(1 + \rho_0) \ln (1 + \rho_0) - \rho_0 \ln \rho_0] \quad (9)$$

where the E_v^0 is the spectral density of absorbed radiation and the ρ_0 is the function of distribution at the point $\eta^* = 0$. But the thermodynamic limit efficiency is of no interest for experimentalists.

The real efficiency η of irreversible process may be of interest to them. It is known that the entropy generation rate \dot{S}_i rises at first linearly [7, 11]

$$\dot{S}_i = \alpha \dot{W}_a \quad (10)$$

where α is constant. One should take into account, the linear changing of the entropy generation rate does not change the form of η^* dependence on E_v , but leads to a parallel shift of the whole curve of η^* along the logarithm absorbed power axis in the Rayleigh-Jeans region and along the η axis in the Wien region [6]. This shift changes the position of the endergonic and exergonic compensation point.

Allowance for nonlinear irreversibility of real process leads to a decrease of η sometimes up to zero in both regions [11].

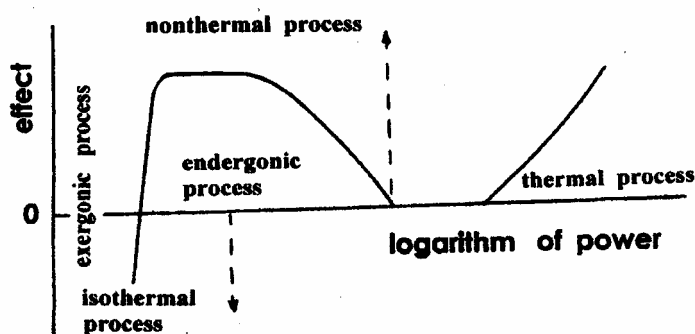

Fig. 2 . Position of isothermal, nonthermal and thermal process in the line of logarithm of absorbed power (Rayleigh-Jeans region).

In the final analysis the η dependence on the absorbed power is complicate. Fig.2 gives it over a wide range of the absorbed power for the Rayleigh-Jeans region. Fig.2 shows different processes (isothermal exergonic process, isothermal endergonic one, nonthermal endergonic one, thermal one) and different dependences (increase, decrease and the lack of any dependence). As is known from experiment [12] the interval of endergonic process may be small (power windowing). Fig. 2 demonstrates the very complicate situation for bioeffect study in the Rayleigh-Jeans region.

The analyse of experimental results on bioeffects of extremely low frequency electromagnetic fields shows that experimentalists study the different ranges of the exciting power, and this is true that they have the different results, including the absence of any effects [4]. The up-to-date experimental results will allow in the future to define the boundary of different processes under the Rayleigh-Jeans radiation in different living systems. Then the general situation will be not like the Cheshire cat.

3. The influence of individual properties of subjects

The Rayleigh-Jeans region has many differences from the Wien one, sending the experimentalists in search of a new apparatus for the experiments. But they must search the new methods of research too, if they want to have the good replicability of the results. The fact is that the role of individual properties of living subject is different in the Wien and in the Rayleigh-Jeans regions.

The indicator of individual properties is the entropy generation rate ${}^0\dot{S}_i$ at the point of endergonic and exergonic processes balance in the real experiments. This point is very known in photosynthesis of green leaves and is called a compensation point. It is studying for human vision processes too. The experimental results for this point allows to calculate the entropy generation rate ${}^0\dot{S}_i$ at this point. In the null point of the real process the dissipative term is equal to the thermodynamic limit efficiency

$$1 - T {}^0\dot{S}_a / {}^0\dot{W}_a = T {}^0\dot{S}_i / {}^0\dot{W}_a \quad (11)$$

and the value of ${}^0\dot{S}_i$ may be calculated. The entropy generation rate ${}^0\dot{S}_i$ is own characteristic of every individual and can change as a function of internal conditions, for example as age. For the group of individuals with different ${}^0\dot{S}_i$ there are the family of curves $\eta = \eta(E_v)$. In Wien region (Fig. 3a) this family permits to find the average value of endergonic effect in ensemble. In Rayleigh-Jeans region the situation is more complicate (Fig. 3b). Averaging over the ensemble gives the zero result as a rule because of the endergonic and exergonic processes are the opposite ones, and averaging over the small group gives the chance result. This is (and will be always) the reason of poor replicability of the experimental results in conditions of low-level of excitation. Knowledge of thermodynamic theory allows to reduce the extent of poor replicability.

Fig. 3. The different role of the number of objects in experiment under the Wien (a) and the Rayleigh-Jeans radiation (b).

The phenomenon of poor replicability near the boundary of endergonic and exergonic processes depends on the sharpness of $\eta = \eta(E_v)$ dependence. This phenomenon is small in Wien region and would be taken into account by Gauss distribution (the inset in right part of Fig. 3a). This factor is great in Rayleigh-Jeans region. In this region the individual properties of subject are the main ones.

I think that the up-to-date figurative popular expression “the Cheshire cat phenomenon” may be in the future the strict scientific term, indicating that the experimentalist studies the initial stage of endergonic effect under Rayleigh-Jeans radiation without the selection of endergonic and exergonic processes. The selection of these processes allows to save from the Cheshire cat phenomenon.

4. Conclusion

Key features of energy conversion in Rayleigh-Jeans region are sharp dependence of efficiency on power and sharp change-over from exergonic process to endergonic one. On the basis of the thermodynamic theory it is thought that the Cheshire cat phenomenon will be seen in pilot studies of bioeffects under other frequencies of Rayleigh-Jeans region and will cloud the work of experimentalists. However the study of nonequilibrium thermodynamics allows them to understand the situation and reduce to zero (or minimum) the Cheshire cat phenomenon. May be, that the experimentalists, who works in the sphere of extremely low frequency, will be more well than the researchers of microwaves, where the microbiological researches are necessarily associated with the ensemble averaging. In such experiment only the experimentalist of extra class can see the effect.

As known, there is the melatonin synthesis reaction, which is the very good object for study. It enables to clear the influence of electromagnetic fields on the processes in animals and human. Melatonin synthesis will be used as a promoter in solution of discussed problem [13].

Abstract

It is very important to understand whether the electric and magnetic fields generated by video display terminals (VDT) are capable to influence on the living organisms. The effect of VDT (17" computer monitor with cathode-ray tube) was studied on viability of *S. cerevisiae* cells, which is the model organism for studying of eukaryotes. The capacity of electric field at the 4 cm distance to the display was 6.4 ± 3.57 V/m, 4.8 ± 2.04 V/m at 30-40 cm, 0.1 ± 0.02 V/m at 100 cm, and zero at 200 cm. Experimental samples were settled on the distance 4, 40 and 250 cm opposite to the central point of the monitor. Some samples were additionally treated with nystatin ($20 \mu\text{g}/10^6$ cells) just after exposure. Viability was determined by the colony forming units.

Exposure of the yeast cells to the VDT radiation only did not change their viability. Same time exposed cells showed much grater sensitivity to the nystatin than the control ones. Effect depended on the distance to the computer monitor and the time of exposure.

These results suggests that physical factors of VDT cause some changes in the yeast cells, which reduce their viability at the presence of the strong stress factors, such as nystatin.

Introduction

The problem of an overload of environment with anthropogenic electromagnetic fields (EMFs) grows together with development of scientific and technical progress and introduction of the newest electrical engineering devices. Anthropogenic EMFs, changing a natural electromagnetic background, can result in the origin of a number of disturbances at cellular, subcellular and molecular levels that reflects in the different diseases (cancers tumors, leukemia, dermatitises, mental decline, and so on) [4, 16]. Researches in this field carried out in the different laboratories of the world behind several directions depending on the frequency characteristics of EMFs. Special attention given to influence on the user of radiation emitted from video display terminals (in particular monitors of computers and TV sets) [3, 12]. Except for a mental fatigue, aggression and depression [16], work with video display terminals (VDT) influences a physiologic state of the user's organism changing frequency of heart rhythms, reducing concentration of melatonin in saliva and increasing maintenance in urine of 8-hydroxydeoxyguanosine, and also the number of leucocytes multiplying in a blood [7, 9, 14]. For today, VDT is possible to consider as a risk factor, which increases probability of origin of disease of skeletal-muscular and visual systems [13], skin [2, 10, 15] and reproductive system [11, 12]. In the publications, which generalize the new data on EMFs effects, absence of unique mind is marked in relation to the mechanisms of EMFs action on living objects. This results in the constant revision and perfection of the already established norms of allowable radiation on the living organism [8].

The situation arisen in the given direction of researches closely linked to absence of the biological system-indicator adequate to revealing of harmful effect of VDT on an organism. Multicellular organisms, because of complexity of their structure, not are able to be the sensors of EMFs action that is why attention of scientists aimed on the use as biosensors of separate cultures of human cells [6] or most studied microorganisms [1]. Microscopic biological objects are more conservative in the reactions to action of any factor, and that is why can be used as indicators of the negative/positive influence of EMFs. There are some rather simple and convenient microscopic modeling systems for research of various processes occurring in the eukaryotic cells, in particular cells of yeast *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* [5].

Studying of EMFs effects with eukaryotic modeling microorganisms will allow to use them as sensory/indicators systems for analysis of the radiation effects from different household devices (computers, mobile phones, the microwave-ovens, and so on) and accordingly to prevent originating the majority of the problems linked to the action of EMFs on the living organism.

The purpose of work was studying the reaction of the yeast *Saccharomyces cerevisiae* cells on the influence of emission of video display terminals.

Materials and methods.

Yeast *Saccharomyces cerevisiae* Y-517 from Ukrainian collection of microorganism at the Institute of Microbiology and Virology of NAS of Ukraine were used for studying. The culture of yeasts was preliminary cultivated on agar medium at 28 °C during 24 h, and then washed off with sterile distilled water, filtered through cotton wool for the separation of pieces of medium and diluted to 10^9 cells/ml ($OD_{540} = 0,75$). Cells were held in the distilled water in order to stop the process of division and accordingly to provide the condition of the work with the same organisms. The optical density of cell suspension measured on a wavelength 540 ± 10 nm in a cuvette with optical way 3 mm.

Received cell suspension divided in equal amounts (5 ml) into the 20 ml glass vials. The vials placed (a) in metallic boxes – for shielding of EMFs and (b) simply in glass vial – for shielding of UV-radiation only.

The source of the electromagnetic fields was 17"-monitor with the cathode-ray tube SAMTRON 75E. The monitor was disposed on a wooden-table on 42 cm higher than system block. The screen of monitor was white-color with maximal brightness and contrast. For studying the influence of physical factors generated by VDT on the yeast cells, the diagrams of electromagnetic emission from the computer monitor were analyzed. Measurements carried out with a dosimeter of intensity of an electromagnetic field – NFM 1, in a range 60 kHz – 350 MHz. The readings were taken at 4, 40, 100 and 250 cm from a surface of the screen and walls of monitors. The exposed samples placed on distance 4, 40 and 250 cm to the center of monitor. Irradiation carried out at the room temperature of 24.5 ± 0.5 °C and day light during maximum 24 h. Cell suspension periodically mixed.

Viability of the exposed and unexposed yeasts cells was determined by the colony forming units in absence and in presence of the fungicidal antibiotic nystatin. Nystatin (2-3 mg) was dissolved in 1 ml of dimethylis sulfoxidum and sterile distilled water added to the necessary volume to receive final concentration of 20 µg of nystatin in 1 ml of solution. This solution used for further researches.

Initially and after 3, 6 and 24 hours yeasts cells from each vial used for determination of viability and sensitivity to the fungicidal antibiotic nystatin. For this purpose 0.1 ml of cells added to 9.9 ml of the sterile distilled water or to 9.9 ml of water containing 20 µg/ml of nystatin getting the concentration of 10^6 cells/ml and mixed it during 10 min. After that, the series of dilutions was done and concentrations 10^3 and 10^2 cells/ml received. From these solutions, 0.1 ml added to the Petri dishes with agar and placed in a thermostat at 28 °C. The colonies counting and data analyses were done after 72 h.

Results and discussion.

Analysis of the yeast *Saccharomyces cerevisiae* viability in the distilled water showed that cells keep during a long time (more than 24 hours) in a wide range of temperatures (20 – 28 °C) stable physiologic state. Necessary to notice, that the opportunity of use of only water medium without admixtures is very important as, at first, simplifies process of carrying out of researches and, secondly, minimizes influence of additional physical and chemical factors, which take place at presence in medium of free ions.

As well as in previous our researches [17, 18] at optimum for yeast *Saccharomyces cerevisiae* conditions of an external environment (temperature, pH, and so on) action of EMFs generated by VDT did not reflect on standard parameters of the growth processes. Microscopy also has not given an opportunity to find any differences between the exposed and control samples.

Same times in the presence of the strong stress-factor, such as fungicidal antibiotic, the negative consequences of electromagnetic emission from the VDT were seen. The data concerning vitality of *Saccharomyces cerevisiae* cells at the presence of nystatin shown in Table 1.

Table 1. Percent of viable cells of *Saccharomyces cerevisiae* Y-517 in the presence of nystatin (20 µg/ 10^6 cells) and in dependence on the distance to the monitor and time of exposure

Values are the mean \pm SD from the minimum three separate experiments.

Time of an exposition, h	Distance to the monitor, cm			The control
	4	40	250	
0	-	-	-	28 \pm 9,9
3	4 \pm 2,8	14,8 \pm 6,7	25 \pm 9,9	28 \pm 9,9
6	12 \pm 1,2	42,5 \pm 5,3	40 \pm 2,2	55 \pm 7,3
24	29 \pm 29,7	22 \pm 4,2	45,5 \pm 3,5	25 \pm 9,9

USE OF MODEL ORGANISM FOR AN ESTIMATION OF VDT EFFECTS

The maximum of activity of an antibiotic and accordingly a minimum of a resistance of the cells were observed at minimal (4 cm) distance from the center of the monitor. After three hours nystatin suppressed growth of 70 % of cells in the control, and in the exposed samples – 96 %, 85 % and 75 % accordingly on the distance 4, 40 and 250 cm. After 6 and 24 hours these parameters reduced that, probably, testifies to increase of stability of cells to action of the external stress-factors of the physical and chemical nature.

It is necessary to note, that after 6 hours in control samples observed substantial increase (on 20 %) of viable cells. The cause of such phenomenon can be in change of some properties of the yeast cells. For example, the stay of living organisms in the distilled water results in decrease of permeability of cytoplasm membranes and cellular walls with the purpose of not allow an efflux of the intracellular compounds. It, in turn, complicates process of penetration and probability of attachment of polyene antibiotic to the molecules of cytoplasm membranes.

After 24 hours, vitality of cells in the controls diminished up to initial parameters while in the exposed samples remained at high level. This can testify to the presence of differences in character of flowing of intracellular processes in the exposed and unexposed yeast cells, what clearly recognized under action of the strong stress-factor such as fungicidal antibiotic.

Table 2. Doses of radiation in a range 60 kHz – 350 MHz from the SAMTRON 75E monitor with cathode-ray tube, V/m

Values are the means.

Distance from VDT, cm	Screen	Left side	Right side	Top side	Back side
4	6,4	15	9	3	7
40	4,5	2	3	3	7
100	0,1	0,5	0,5	0,5	0,5
250	0	0	0	0	0

The ability of cells to survive under action of an antibiotic is in direct dependence on the distance to the display. The data in Table 2 present doses of radiation received for the monitor with cathode-ray tube SAMTRON 75E used during experiments. Seen, that the intensity of EMFs in the same manner significantly decreased with the distance. Both these facts may suggest that electric fields generated by VDT may play a key role in the influence on the biological objects. It is very important to note that on the distances of 200 and 250 cm from the screen of the display the intensity of EMFs in the range 60 kHz – 350 MHz are equal zero, but biological action of VDT emission still obvious.

Summary

EMFs generated by VDT had the negative influence on the modeling organism *Saccharomyces cerevisiae* that especially seen in the presence of the stress-factor (antibiotic nystatin). Cells of *S. cerevisiae* Y-517 provides unique tools for understanding environmental effects on cellular systems and can be biological sensors at development of the bioanalytical systems for analyses of bioeffects from different electromagnetic devises such as computers, TV sets, mobile phones, microwave ovens and so on.

Other microorganisms may also be sensible to the action of the electromagnetic fields generated with different laboratory or industrial equipments. Therefore, during work with microbiological objects it is necessary to take into account and eliminate the possible influencing of emissions from VDT for avoidance of errors at the estimation of results of researches or during biotechnological processes.

ABSTRACT

The controversy over the safety of mobile phones and their base stations continues despite many years of study into the non-thermal interactions of radio frequency electromagnetic fields (RF-EMF) with biological tissue. This study exposes rat mesenchymal stem cells (MSC) to RF-EMF in a Crawford TEM cell at 900MHz. A robust dosimetric analysis of the exposure system is performed to determine the configuration which will optimise system efficiency, minimise heating and provide the most uniform specific absorption rate (SAR) across the cell monolayer. Data from exposure of MSC to continuous wave, GSM and intermittent (5mins on/ 10mins off) 900MHz RF-EMF is presented. SAR levels are all below the 2 W/kg ICNIRP guidelines for public exposure. Recruitment, proliferation and differentiation of MSC are measured using the CFU-f assay under osteogenic (bone stimulating) conditions. No effect is observed. Additionally, hydrogen peroxide is used as a model of oxidative stress in order to determine if GSM 900MHz RF-EMF is a cofactor in stressing cells. Again, no effect is observed on MSC recruitment, proliferation or differentiation into bone.

INTRODUCTION

There is continuing widespread debate concerning the possible biological effects of radio frequency electromagnetic fields (RF-EMF) emitted by mobile phones [1]. In-vitro studies are useful because they provide a simplified biological model that allows the exposure parameters to be more precisely defined and controlled compared with in-vivo exposure. This paper presents dosimetric analysis of a Crawford TEM cell [2] at 900MHz using finite difference time domain (FDTD) modelling, to determine the optimum dish separation and height off the septum, and level of culture medium so as to maximise both the power deposited and its uniformity in a monolayer of mesenchymal stem cells (MSC) in the bottom of each culture dish. A similar system has previously been used by the authors to expose human leukocytes in suspension [3]. Specific absorption rates (SAR) are calculated in the ~1mm layer of culture medium at the dish bottom using both in-house [4] and commercial SEMCAD [5] software, with subsequent experimentation based on the results using the fibroblastic-colony forming units (CFU-f) assay to quantify any effects on stem cell recruitment, proliferation and differentiation.

Exposures using continuous wave (CW), GSM type bursts and intermittent carrier (5 mins on / 10mins off) were performed at 900MHz, whilst maintaining a constant ambient temperature of 37°C. In order to ascertain if such non-thermal RF-EMF could also act as a co-factor in causing an effect, a common in-vitro model of oxidative stress was used. Hydrogen peroxide (H₂O₂) is an oxidative agent, known to cause stress to cells, and a concentration of this was added to the cells, sufficient to affect them with no RF-EMF applied whilst at the same time not killing them all.

Materials and Methods

RF Equipment

Briefly, the exposure system in Fig.1 utilises a GSM handset in engineering test mode as a source, which is then amplified and routed through a travelling wave TEM cell. Environmental control is achieved by placing the TEM cell inside an incubator which maintains 95% humidity, 37°C, and 5% CO₂, and real time thermal monitoring of internal TEM cell temperature is provided by a fluoroptic thermometer. To expose at higher SAR values non-thermally the system needs to deliver high efficiency, measured in W/kg per W of input power, while minimising the thermal load. Air fans are therefore attached to the TEM cell at its tapered ends to increase cooling. A second identical TEM cell provides sham exposure for control purposes.

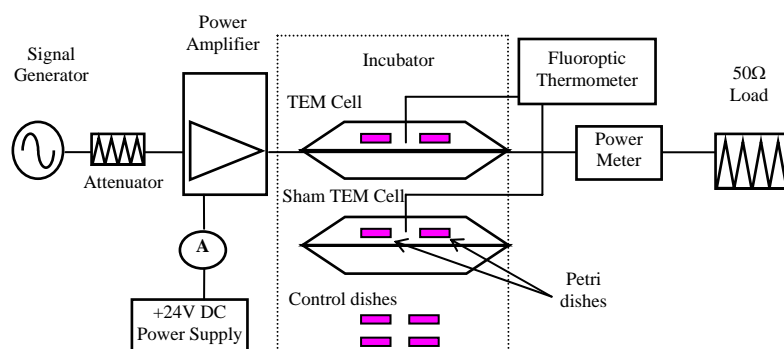

Figure 1: Schematic of Exposure system.

Fibroblastic Colony Forming Unit Assay

The fibroblastic colony forming unit (CFU-f) assay is a cell culture model which uses primary bone marrow seeded at low density. The low density seeding allows the cells to form colonies without contact inhibition. Each colony is assumed to grow in isolation from the others, and be derived from a single MSC, and the number of colonies is a measure of the number of colony forming units present in the original bone marrow cell suspension therefore. This MSC proliferates and differentiates depending on the stimulus [7] which can be chemical or physical. The colonies are then sequentially stained for alkaline phosphatase, calcium and collagen, which are all markers of osteogenic differentiation.

Primary BMSC were extracted from the femur and tibia of adult Wistar rats. Bone marrow was extracted using the method published in [7]. Briefly, the leg bones were removed and the bone marrow extracted and re-suspended in 1ml of Dulbecco's Minimum Essential Medium (DMEM) to create a single cell suspension. Cells from all bones were then pooled and 10ml supplemented DMEM per bone was added to create primary bone marrow suspension. The supplements added to the DMEM were 10% Serum Supreme, 1% Ultraglutamine, 1% Penicillin/Streptomycin and osteogenic stimuli, 50µg/ml ascorbic acid and 10⁻⁸M dexamethasone.

The primary bone marrow suspension was used to seed the 90mm Petri dishes at a density of 1.2×10^6 cells, in 10ml supplemented DMEM. RF-EMF exposure was for five 3-hour periods over 5 consecutive days, after which the medium was changed, and thereafter twice a week. Cells were then cultured for a total of 16 days, after which the plates were washed in PBS and fixed with cold 70% industrial methylated spirits (IMS). After fixing, they were immediately histochemically stained for alkaline phosphatase (APase) activity, and then sequentially for calcium-positive, collagen-positive and total colonies. After each staining, the cultures were digitally photographed and the subsequent photographs processed to allow for automatic analysis. The images were then analyzed using Bioimage "Intelligent Quantifier" image analysis software [8]. The software counts the colony number and calculates each colony area. This data was subsequently analyzed using SPSS for significance testing using the ANOVA test at $p < 0.05$.

EFFECT OF 900MHZ EM RADIATION ON STEM CELLS

As a result of the dosimetric analysis (see results section), the required medium height in the Petri dishes had to be 10mm (60ml medium) instead of the standard 2-3mm (10ml medium). However, this amount of fluid above the monolayer hinders the gas exchange between the monolayer and atmosphere, causing hypoxia and cell death. In order to comply with the dosimetric analysis therefore, the extra 50ml of medium was added for the duration of the RF exposure and the hour-long temperature equalization pre-exposure period. Immediately after RF-EMF exposure, this extra medium was then removed from each dish and stored separately at 4°C overnight until the next exposure the following day, when it was returned to the same dish. This is because it has been shown that non-adherent cells in the medium are crucial to MSC recruitment and proliferation [7]. After the initial five days exposure however, this extra medium was no longer used. To control for the effect of the extra medium, a set of dishes were placed outside the TEM cells with 10ml of medium, in contrast to the dishes inside the exposed and sham exposed cells which contained 60ml.

The protocol for co-exposure of the MSC to GSM modulated RF-EMF and H₂O₂ was the same as for exposure to RF-EMF alone, with the following modifications. A third control group was added, where MSC were exposed to H₂O₂ alone, outside of the TEM cell, and a concentration of 10⁻⁵M H₂O₂ was added to the MSC immediately before placing them in the TEM cells.

Results

Dosimetric analysis

The aim of the dosimetry analysis was to optimise the system to give high SAR efficiency and uniformity. The use of both in-house and commercially available SEMCAD FDTD code provides valuable control data for accuracy assessments, and also expedites analysis since the in-house code runs on a Unix super-cluster rather than the standard Windows PC, which our version of SEMCAD is configured for (although a Unix version is available). Uniformity can be quantified as the ratio of standard deviation of SAR to the mean (%SD), and is calculated for the bottom layer of voxels in a dish. Acceptable uniformity is 30% SD or less [6]. No software currently available can realistically grid to the micrometer scale (the thickness of the monolayer), however a grid size as small as 0.3mm is possible with reasonable simulation time in SEMCAD, which is better than the resolution achieved using physical measurements. It is assumed for the purposes of dosimetry that the SAR in this bottom layer of voxels is representative of the SAR in the monolayer. The volume of medium in the tissue culture dish affects the SAR uniformity and efficiency, as does its distance from the septum, as shown in Fig.2 for 1V peak excitation of the TEM cell. Here our in-house FDTD code has been used to calculate the SAR in the bottom 1mm layer of medium contained within a 90x18mm circular dish with a lid. The SAR clearly increases with medium height (h) and elevation above the septum (z), with bigger changes observed at higher medium levels, whereas the variation of uniformity with elevation converges towards a standard trend as the medium height increases. A medium level of h = 10mm was therefore chosen, at z = 5mm off the septum. A smaller elevation of z = 1mm would have provided the best uniformity of exposure, but with a reduced mean SAR. However, the CFU-f assay requires medium heights of 3mm or less in order to allow adequate oxygen diffusion to the stem cells. This would reduce the SAR by about 10dB and degrade the uniformity, so the medium height was temporarily increased to 10mm for the duration of the planned exposure (3 hours plus 1 hour warm up time) as mentioned previously.

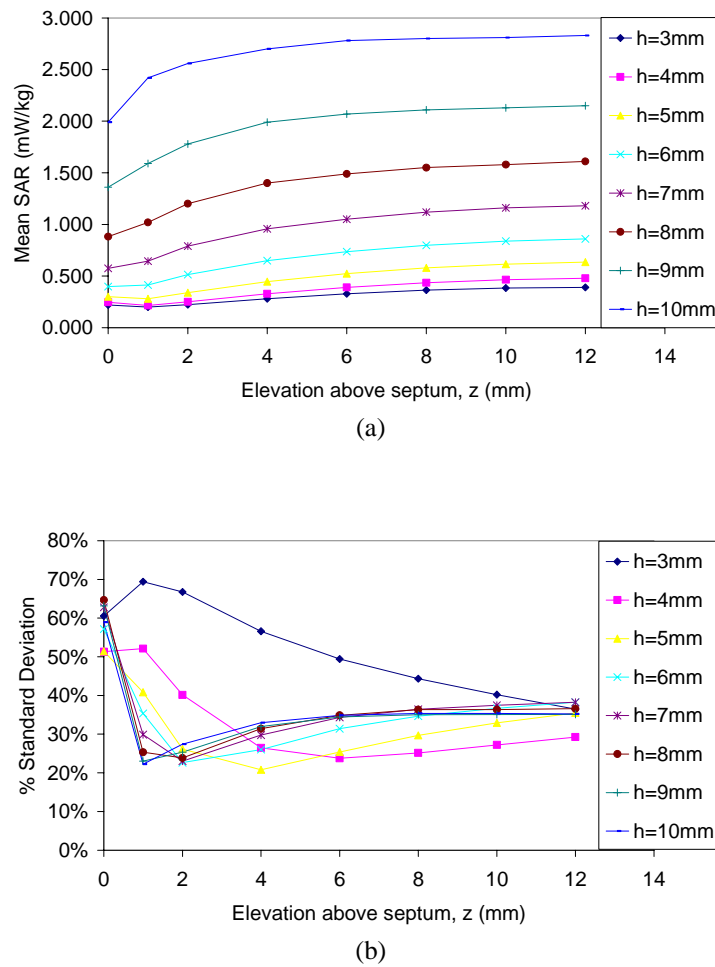

Figure 2: Variation of (a) mean SAR and (b) SAR uniformity in bottom layer of culture medium as a function of dish elevation (z) for various medium heights (h).

Figure 3: Comparison of in-house FDTD code and SEMCAD. Mean SAR for the whole medium volume varying with elevation above septum ($h=10$ mm).

To increase the number of samples exposed simultaneously, two dishes were used, and SEMCAD was now employed to further refine the dosimetry and to investigate the effect of separation between the dishes on SAR and uniformity. As seen in Fig.3 our in-house and SEMCAD code agree reasonably well for a control example. Fig.4 shows the field interacting with the dishes to produce both dissimilar and non-uniform SAR distributions in the bottom layers. Increasing the separation reduces the coupling

EFFECT OF 900MHZ EM RADIATION ON STEM CELLS

and makes the distributions more alike, but edge effects from the tapered ends of the TEM cell begin to influence the uniformity at the furthest separation. The best uniformity is found at a separation of $s = 50\text{mm}$, where the mean SAR's in the bottom layers and their %SD's are similar, which allows the dishes to be treated almost identically. The CFU-f assay uses imaging software to analyse the colony formation of MSC, which excludes the outer 1mm of the dish bottom as the imaging process produces artefacts here. If this area is not taken into account the SAR values are slightly higher than those in Fig.4, with mean = 2.61 mW/kg , %SD = 31.9% for dish 1 and mean = 2.58 mW/kg , %SD = 32.7% for dish 2. The effective SAR efficiency is $\sim 1.0\text{ W/kg}$ per Watt of TEM cell input power.

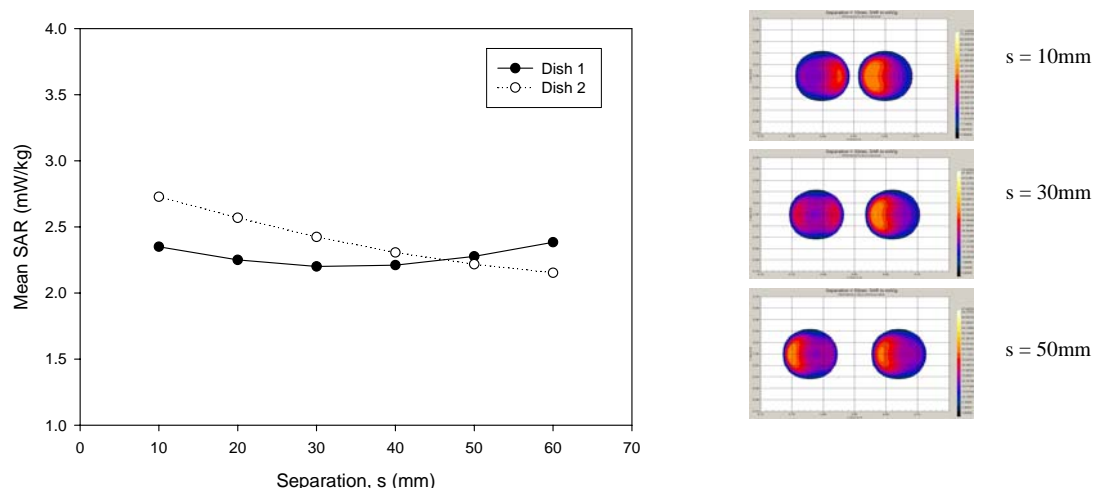

Figure 4: Variation of mean SAR in bottom layer of medium for 2 dishes as a function of separation (s) ($h = 10\text{mm}$, $z = 5\text{mm}$), with example SAR contrast plots shown at $s = 10\text{mm}$, 30mm and 50mm .

Biological Results

Having determined the optimum elevation, medium level and separation for the two dishes, MSC were then exposed to 900MHz CW, GSM and intermittent CW (5mins on/10mins off) RF-EMF. Averaged SAR values were 1.6 W/kg for CW, 1.6 W/kg for GSM and 0.9 W/kg during the on period for the intermittent exposure (further work is planned with a higher SAR for the intermittent exposure scheme). After consecutive histochemical staining and image analysis, colony numbers and areas were calculated, and are shown in Figs.5-7.

Figure 5: Colony number and area for a representative CW 900MHz RF-EMF exposure. ($n = 3$ or 4)

Figure 6: Colony number and area for a representative GSM 900MHz RF-EMF exposure (n = 4)

Figure 7: Colony number and area for a representative intermittent 900MHz RF-EMF exposure (n = 4).

Effect of simultaneous oxidative stressing by hydrogen peroxide

MSC were then co-exposed to 900MHz GSM RF-EMF at an averaged SAR of 1.6W/kg and to 10^{-5} M H_2O_2 in the same optimized configuration, and the results are shown in Fig.8.

Figure 8: Colony number and area for a representative co-exposure of 900MHz GSM RF-EMF and H_2O_2 exposure (n = 4).

Discussion

Generally no significant differences in colony numbers or areas between exposed and sham exposed MSC are evident in Figs.5-7, although there does appear to be borderline differences in colony numbers between some controls and sham exposed MSC in Fig.7. This is to be expected, given the difference in conditions between these groups. Generally, in the control group, the colony number is slightly reduced, and the colony area slightly smaller. This suggests that the extra handling and medium levels of the exposed and sham groups could be affecting both the recruitment and the proliferation of the MSC. This is probably due to them receiving higher amounts of growth factors from the larger volume of medium. Another behavioural difference was seen in the distribution of the colonies; in the control group the colonies tended to be in the middle of the dish, whereas they were more evenly spread in the exposed and sham groups. This is likely to be due to moving the dishes in and out of the TEM cell, as well as stirring when the extra medium is added.

Diem et al, [10] used intermittent exposure to show that 1800MHz RF-EMFs could cause DNA breakages in both cultured human diploid fibroblasts and cultured rat granulosa cells at non-thermal levels after 16 hours continuous exposure (SAR =1.2 and 2 W/kg). Our experiments exposed MSC to daily 3 hour periods of intermittent RF-EMF for 5 consecutive days, at an SAR of 0.9 W/kg but found no significant effects. As the SAR levels for the data shown here is lower than that of [10], further exposures are ongoing at higher SAR's. While caution is required in comparing different frequencies, different cell types, and the responses of cultured and primary cells, this does suggest that a long continuous exposure is required to induce any effect, rather than an equivalent cumulative exposure.

Oxidative stress is known to play a role in stem cell differentiation [11]. It has been shown that there are interactions between oxidative stress levels and the ability of the stem cells to proliferate, and that antioxidants can increase the total number of cells. Stolzing and Scutt [11] showed that H₂O₂ reduces both alkaline phosphatase expression and total colony number. As expected, in our experiments H₂O₂ alone generally significantly reduced MSC number, as well as their proliferation, as shown by the reduced colony numbers and sizes in Fig.8. This also helps corroborate the assaying procedure itself. Co-exposure with RF-EMF generally showed no additional effects compared with sham exposure, although some significant differences were again observed between H₂O₂ MSC colony numbers outside and inside the TEM cells. Finally it is worth noting the anomalous significant differential collagen area of H₂O₂ stressed MSC when exposed to GSM compared to sham exposure, although no conclusions may be drawn from this one result.

SUMMARY

A dosimetric analysis has been performed using a TEM cell based exposure system for in-vitro stem cell cultures, with subsequent experimentation based on the results. Optimal positioning and filling of the cell culture Petri dishes for maximum mean SAR and uniformity in the stem cell monolayer was calculated using both in-house and commercial FDTD modelling software. MSC recruitment, proliferation and differentiation were not affected by CW, GSM or intermittent CW exposure to 900MHz RF-EMF, even when the MSC were co-exposed with H₂O₂.

ACKNOWLEDGEMENTS

We would like to thank Dr A. Stolzing for her help in the preparation of this manuscript.

BIOPHYSICAL STUDIES OF LIGHT INTERACTION WITH MEMBRANE MODEL SYSTEMS BASED ON CHLOROPHYLL *a*

LAURA TUGULEA

Faculty of Physics - University of Bucharest
P.O.Box MG-11, Bucharest-Magurele, 077125 ROMANIA

Abstract

The interaction of light energy with plants results in the most important process on earth: the photosynthesis. Biophysical studies on membrane model systems bring relevant insights for *in vivo* primary reactions in photosynthetic membranes. Liposomes with chlorophyll *a* are biomembrane models, providing a hydrophobic environment for chlorophyll *a*, the major pigment in photosynthesis. The spectral features of chlorophyll *a* allow its use as sensor for physical properties of liposomes and for specific molecular interactions in the liposome bilayer. Supported lipid bilayers (SLB) can be obtained by deposition of liposomes on solid surfaces, using different supports. This new approach provides access to basic aspects of membrane biophysics and represents the basis for developing different applications. The objective of our work was to obtain SLB with chlorophyll *a* and to use chlorophyll as a marker in biophysical studies on these structures. Specific interactions occurring inside the lipid membranes, exposed to light (in the visible range of electromagnetic radiation) have been studied, using the strong absorption and emission of chlorophyll *a*. The most interesting application of SLB with chlorophyll *a* is represented by devices for light energy conversion, mimicking photosynthesis. Photovoltaic devices based on chlorophyll *a* are presented.

Introduction

Liposomes are phospholipidic vesicles which enclose an aqueous volume. They have been under extensive investigation for more than 20 years as carriers for the improved delivery of a broad spectrum of agents: chemotherapeutic agents, imaging agents, antigens, chelating compounds, hemoglobin and cofactors, lipids and genetic material [1]. Liposomes can be prepared so that they can entrap certain quantities of materials both within their aqueous compartment and within the membrane.

The value of liposomes as membrane model systems derives from the fact that they can be prepared of natural constituents and the liposome membrane forms a bilayer structure which is almost identical to the lipid portion of the natural cell membranes. The similarity between liposomes and natural membranes can be increased by chemical modification of the liposome membrane and can be exploited in different applications, both *in vivo* and *in vitro*, mimicking successfully the behaviour of natural membranes. Apart from their chemical constituents, which determine such properties as membrane fluidity, charge density and permeability, liposomes can be characterized by their size and shape. They can range in size from ~ 25 nm to 1000 nm or greater, which equals the dimensions of a living cell. Alternatively, liposomes can be prepared of entirely artificial components, chosen for their improved chemical properties.

The liposomes with chlorophyll *a* (Chla) are excellent models for biomembranes, specifically for photosynthetic membranes and are successfully used to study the influence of different agents on the bilayer structure at molecular level [2-5]. Chlorophyll *a* is a "valuable" molecule, but insufficiently exploited in biotechnological applications. The strong visible absorption and fluorescence of Chla allow its use as a sensor for the interactions at molecular level and as a fluorescence marker. It has been shown that Chla has also radioprotective, antimutagenic and anticarcinogenic activities. Chlorophyll's antioxidant

properties could be partly responsible for its protective effects in natural and artificial structures.

The deposition of liposomes on solid surfaces, by different techniques, conducted to a new approach: supported lipid bilayers (SLB) [6-8]. This new approach provides access to basic aspects of membrane biophysics and molecular ordering and may constitute a strategy for developing biotechnological applications [9].

Because it turns out that liposomes of different size require completely different methods of manufacture and because different applications demand the use of liposomes within particular size, an objective of our work was to prove that the spectral features of Chla allow its use as a sensor for physical properties of liposomes (size, shape, molecular dynamics).

The main objective of the present work was to obtain stable Chla-liposomes and supported Chl-lipid membranes and to characterize the structures by using Chla as a marker and molecular sensor. Using the strong absorption and emission of chlorophyll *a*, specific interactions occurring inside the lipid membranes, exposed to light (in the visible range of electromagnetic radiation) have been studied. A particular application of SLB with chlorophyll *a* was developed by manufacturing devices for light energy conversion, mimicking the primary act in photosynthesis (separation of charges under the light irradiation).

Materials and Methods

Chl a - Liposomes preparation procedure

Chla-liposomes were prepared using the thin-film hydration method. The lipid and Chla were dissolved in chloroform, with Chla/lipid molar ratio varying from 1/100 to 1/10. Different types of thin films were obtained, by vacuum evaporation, using different lipids: β -stearoyl-oleoyl L-phosphatidylcholine (SOPC), dimyristoyl phosphatidylcholine (DMPC), dioleoyl phosphatidylcholine (DOPC) or soybean lecithin. Chla was prepared from fresh spinach leaves by Strain&Svec method and checked for purity (absorption and fluorescence in VIS). The hydration (2 hours) of the lipid-Chla film was done by adding phosphate buffer, pH in the range: 6.2 - 7.6, in a rotary evaporator (BIOBLOCK SCIENTIFIC – Heildolph 94200, 60–90 rpm). Multilamellar vesicles (MLV) were obtained by mechanical dispersion (VIBRAX stirrer, 200rpm) of the hydrated films (30'). Intermediate unilamellar vesicles (IUV) or small unilamellar vesicles (SUV) were obtained from the multilamellar liposomes by using the exposure to ultrasonic in a bath (Branson 1210), above lipid T_c , for variable periods. For obtaining a homogenous population of liposomes, the suspension was collected after a centrifugation at 100000 g for 1 h.

Formation of supported lipid membranes

Chla-SLB have been obtained by adsorption method. A drop of Chla-SUVs suspended in phosphate buffer was spread on different solid supports: Silicon wafers and semitransparent SnO_2 or ITO glass. Chla-SLBs are formed by spontaneous deposition of Chla - SUVs.

Chla-SLBs on n-doped silicon wafers have been covered by a semitransparent gold electrode (1.5 mm² measurable area). Thus a photovoltaic device, sandwich type, was manufactured.

Spectral measurements

The optical absorption spectra were obtained on a double beam UV - VIS spectrophotometer Lambda 2S Perkin Elmer & PECSS software. A computer assisted Aminco Bowman was used for recording the fluorescence spectra. A front face geometry, on Perkin Elmer LS 55 fluorometer, was used for measuring the fluorescence, collected at 45° from the solid support.

Photo-electrical measurements

The irradiation of Chla-liposomes in suspension was done by using a halogen lamp (650 W), a convergent lens and a water filter (5 cm thick). The photovoltaic devices were illuminated, within the visible range of the electromagnetic spectrum, by using a halogen lamp and a grating monochromator (Oriel). For the electrical measurements (photocurrents) a dedicated software and a Keithley 6517 electrometer were used.

Results and discussions

Characterisation of Chla - liposomes by light absorption in VIS

The liposomes will scatter light in the visible range of the electromagnetic spectrum, if their dimension is in the range of the respective wavelengths. Typical diameters for MLVs range between 100nm and 1000nm, each vesicle consisting of five or more concentric lamellae. Typical dimensions for SUVs are 15 nm (pure egg lecithin liposome in normal saline) or 25 nm (for DPPC liposomes). IUVs have

BIOPHYSICAL STUDIES OF LIGHT INTERACTION WITH MEMBRANE MODEL SYSTEMS

the order of magnitude around 100nm, according to R.R.C. New [1].

In order to do a rapid estimation of the size of the lipid vesicles, the absorption changes in the VIS spectra of Chl *a* were monitored and some spectral criteria were established. Inspecting the absorption spectrum of Chl *a* in different liposomes, presented in Figure 1, major differences can be observed as regarding the base line (background) of the spectra. The main absorption bands of Chl *a* (Soret band and red band) are present in the spectrum and confirm the localisation of the porphyrin ring of chl *a* at the lipid-water interface in the vicinity of polar lipid heads (the red band is shifted to longer wavelengths as comparing with solution, i.e. 670 nm).

Figure 1. Absorption spectra of Chl *a* liposomes

A $1/\lambda^4$ dependence of the baseline was observed in VIS absorption spectra of the Chl *a*-unilamellar vesicles (SUV or IUV), suggesting that the size of the vesicles is small enough to act as point sources of scattered light. And it was observed that smaller liposomes scatter shorter wavelengths (blue) more intensely, while larger liposomes scatter long (red) wavelengths. It is the case of Rayleigh scattering, applying to particles with a radius less than the wavelength of light / 20 ($R < \lambda/20$) [10]. The increase of the background scattering observed in the stability studies can be explained by the aggregation or fusion of the vesicles. The larger vesicles formed by aggregation strongly scatter light in comparison with the non-aggregated vesicles obtained after sonication.

Assuming a Rayleigh scattering, the over-estimated absorbances values can be corrected for the

Figure 2. Corrected spectra of Chl *a* liposomes in suspension, after centrifugation

contribution of light scattering on the basis of the OD measured at 325nm, where the scattering is the sole contributor to the O.D. (11):

$$(OD_{\lambda})_{corrected} = (OD_{\lambda})_{measured} - (OD_{325})_{measured} \times (325/\lambda)^4$$

In Figure 2 the corrected spectra are presented for 2 cases: supernatant and sediment, obtained after the centrifugation of Chla-liposomes. The suspension of Chla-liposomes (SUVs) was manufactured as described above, by sonicating the MLVs. By ultracentrifugation, the remained large vesicles are deposited on the bottom of the tube and a homogenous population of liposomes remains in the supernatant. The correction by the above formula of the absorption spectra works very well in the case of the supernatant, but does not correct the base line in the case of the sediment. As a conclusion, the average diameter of the liposomes in the homogenous population is around 60 nm.

Therefore, the spectral analysis of Chl a- liposomes, using the spectral properties of Chla, leads to a rapid monitoring of the liposome preparation. The Chla-liposomes prepared as described above are unilamellar and have diameters in the range 40-100 nm. The nature of lipids and pH value of the buffer are influencing the dimension of liposomes. The neutral pH values proved to be the best as concerning the stability of liposomes [12].

The influence of the lipid nature on Chla –liposome was also investigated. Figure 3 presents the normalized absorption spectra (corrected for the baseline) of Chla- IUVs, obtained by using different lipids. The background absorption is depending on the lipid nature. The difference between DMPC and DOPC is the presence of unsaturated acyl chains in the case of DOPC, thus providing a different environment for Chla in the lipid bilayer. This explains the lower background and therefore the smaller dimension of the DOPC liposomes.

Figure 3. Absorption spectra of Chla- IUVs

Stability studies on liposomes with Chl a were performed by monitoring the changes in the Chl a spectra for different factors. The photooxidation of Chl a was monitored by comparing the absorbance ratio in the Soret band $O.D_{438}/O.D_{416}$. A correlation between Chl a oxidation and lipid oxidation was also observed by performing VIS and UV spectroscopy on the lipids - Figure 4.

BIOPHYSICAL STUDIES OF LIGHT INTERACTION WITH MEMBRANE MODEL SYSTEMS

Figure 4. Absorption spectra of Chla - IUVs in VIS (a) and UV (b)

Light effect on liposomes with Chl a

In order to monitor the effect of light on Chla incorporated in liposomes as compared with Chla in solution (ethanol, polar solvent), aliquots of 4 ml suspension of Chla- liposomes were irradiated using a halogen lamp (white light). In order to prevent heating of the solution and consequences, a water filter was interposed between the sample and lamp. The irradiated cuvette was monitored by measuring the absorption spectrum, every 10 minutes. For comparison, Chla in ethanol solution (the same concentration as in the liposomes) was irradiated and monitored in the same conditions.

The combined effect of oxygen and illumination on the exposed liposomes was monitored by 2 spectral criteria: the ratio of absorbance in the Soret band of Chla (OD 438/ OD 416) and photobleaching % (at the maximum in red, 670 nm). The results are presented in Figure 5, for two cases: pH= 6.2 and pH= 7.35. In both cases, the photoxidation of Chla is pleading for the fact that Chla is photobleached by a slower rate when incorporated in the lipid bilayer.

Figure 5. Dependence of spectral parameters upon illumination time

Formation of Chl a-supported lipid membranes:

The deposition of liposomes on solid surface was accomplished by the adsorption technique. Different events could take place in the process of unilamellar vesicles adsorption on the surface [9]:

- interaction of vesicles with other vesicles and with the substrate
- fusion and rupture of vesicles/ rupture of individual vesicles
- transformation of surface bound vesicles in a continuous supported lipid bilayer.

The concentration quenching of Chla fluorescence, in a suspension of Chla-SUVs, as presented in Figure 6,

could be explained by two possible mechanisms: transfer of energy or formation of molecular non-fluorescent Chla aggregates. The second mechanism could be considered in the case of liposome fusion or rupture of vesicles: Chla inserted in the lipid bilayer achieves more freedom to self-aggregate in fused or ruptured liposome membranes. Following this result, the optimum concentration for liposome adsorption was estimated.

Figure 6. The dependence of Chla fluorescence on concentration, in a suspension of Chla-SUVs ($\lambda_{exc}=430$ nm, $\lambda_{em}=680$ nm)

To monitor the adsorption of Chla-liposomes on solid supports, the Chla absorption and emission properties have been used. In figure 7, the absorption spectra of Chla both in liposome suspension and on ITO covered by Chla-SLB are represented. The spectra are very similar. The red maximum is at 670 nm in both spectra, leading to the conclusion that after deposition on the solid support, Chla remains in the same environment as in the liposomes, i.e. with the porphyrin ring in the vicinity of lipid polar groups.

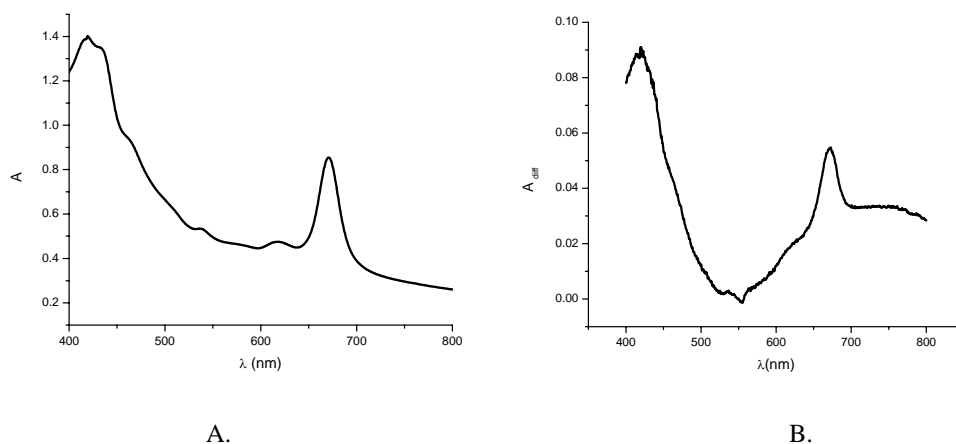

Figure 7. Absorption spectra in VIS range

(A) Chla-SUVs in suspension, (B) Chla-SLB on ITO (ITO absorption was extracted graphically)

Also the emission spectra of Chla-liposome in suspension as compared with the Chla-SLB on silicon wafer, presented in Figure 8, are sustaining the above conclusion, that Chla is keeping the place in the lipid bilayer when liposomes are spread on the solid support surface.

($\lambda_{exc}=430$ nm)

Sensitization process at chlorophyll/Si hetero-junction

As already mentioned in the introduction, SLBs are envisaged as useful new structures for different biotechnological applications. By manufacturing a photovoltaic device, based on Chla-SLB deposited on Si wafer, some promising preliminary results have been obtained. The action spectrum presented in figure 9 (the photocurrent plotted as function of the wavelength of the illumination light) is pleading for an effect of sensitization at Chlorophyll/Si hetero-junction.

Figure 9. Action spectrum of the sandwich type cell (Si/Chla-SLB/Au)

Summary

Chlorophyll a incorporated in the liposome lipid bilayer was used to monitor the formation of both Chl- liposomes and supported Chl-lipid membranes.

The strong visible absorption and fluorescence of Chlorophyll a allow its use as a sensor for the interactions at molecular level and as a fluorescence marker.

Spectral criteria have been developed in order to monitor the size and shape of Chla-liposomes, the oxidation state of the components and for studying the effect of irradiation with light (VIS range).

Interaction of Chla with light and the Chla absorbance and fluorescence properties were successfully used to monitor the supported lipid membranes on ITO and Si substrate.

LAURA TUGULEA

Preliminary photo-electrical measurements are pleading for successful utilization of supported Chl lipid membranes in building up photovoltaic devices using Chl a as a photo- sensitisation factor.

THE EFFECT OF TERAHERTZ RADIATION OF A FREE ELECTRON LASER ON THE LYOPHLIZED SAMPLES OF OX SERUM ALBUMIN

N.L.LAVRIK, E.M.NEMOVA

INSTITUTE OF CHEMICAL KINETICS AND COMBUSTION SBAS,
NOVOSIBIRSK, RUSSIA
lavrik@ns.kinetics.nsc.ru

The lyophilized samples of ox serum albumin (OSA) were IR irradiated at $\lambda = 120 - 140$ mkm by a free electron laser of a power of 130-280 mw. The analysis of IR absorption spectra indicates a decrease in both the optical density of the bands of characteristic frequencies ($2700 - 3100 \text{ cm}^{-1}$) and the value of background determined by scattering intensity. The analysis of UV absorption spectra indicates a decrease in the optical density of irradiated samples at $\lambda = 270$ nm as compared with the non-irradiated ones. The thermal heating of samples caused an increase in the scattering of IR spectra and no changes of absorption value in the region of characteristic frequencies and UV absorption spectra. The influence of terahertz radiation was didn't observed for water solution of OSA. The observed laser effects are interpreted in the framework of the hypothesis of the existence of photochemical destruction, laser swelling and ablation.

Introduction

Studying the influence of interaction between electromagnetic terahertzian radiation, THz (70 - 240mkm), and bioobjects is actual because of a feasible effect of this radiation on their functioning and structure [1-2]. However, the total number of works devoted to this problem is rather small [3]. A direct study on the interaction between terahertzian radiation and biomolecules is presented in a limited number of works [4-8]. Thus, in [5] it is shown that the irradiation of horse-radish DNA molecules, lysocyme and peroxidase leads to soft ablation under free electron laser irradiation ($\lambda = 100-200$ mkm, pulse duration 50 pc, frequency 5,6 MHz, mean power 200 W). The existence of soft ablation is assigned to the fact [7] that the irradiated protein partially preserves a functional activity.

It is concluded then [8] that the irradiation of the lyophilized preparation of ox serous albumin (OSA) causes changes (deformation) in a secondary structure. In this work, a pulse laser with a generation wavelength of 90 mkm and a pulse energy of 5 mJ was used. The values of doses were varied from 0.2 to 3 J. This information was extracted from changes of the fluorescence properties of the probe whose interaction with an OSA molecule was dependent on the irradiation dose obtained by the OSA molecule. The deformation of substance structure under laser pulse can be followed by swelling and ablation [9]. Thus, according to [9] the action of laser radiation is likely to lead to the swelling of OSA samples.

The swelling (the formation of tubercles at the irradiated surface), i.e., the deformation of object macrostructure, can actually cause direct changes in the electron characteristics of the OSA molecule. Thus, of interest is to observe changes in the IR and UV absorption spectra of OSA samples under terahertzian radiation because these spectra contain direct information on the electron properties of the molecule under study. The goal of the present work is to compare the IR and UV absorption spectra of OSA samples before and after THz irradiation.

Materials and Methods.

The lyophilized OSA preparation of the firm «PPP» was used without repurification. The starting preparation was represented by 3 mm flat plates. The samples were irradiated in teflon (fluoroplast) cells. The thickness of the windows was 3 mm. The sample irradiated (the preparation was preliminarily grinded in an agate mortar) was spread throughout a window with 50 mkm cylindrical cavities of a diameter of 30 mm.

A free electron laser (FEL) [10] produced terahertzian radiation with the parameters $\lambda = 130-140$ mkm, a pulse duration of 50 ps, a frequency of 5,6 MHz, and a mean power of 200 mW. The time of irradiation was 3, 6 and 9 min which corresponded to doses of 36, 72, and 108 J, respectively. The power was controlled by an power meter IMO-2. The laser beam half-width was 8 mm.

The thermal heating was realized by locating a cell in a thermostat at a given temperature under irradiation of a thermal gun. The heating temperature was measured using a differential thermocouple. The samples were heated to 55°C .

The IR spectra of irradiated and test samples were analyzed in the cells used for irradiation. A Fourier-spectrometer ("Bruker") was employed for analysis. The UV spectra of irradiated and test samples were analyzed using aqueous OSA solutions whose concentration was 1mg/ml. The solutions were prepared by dissolving the weighted portions of irradiated and non-irradiated OSA powders in deionized water. The UV absorption spectra were obtained using a "Hewlette-Packard" spectrometer.

Results and discussion

Figure 1a shows the IR absorption spectrum of albumin powder (control). The range of characteristic frequencies from 2700 to 3500 cm^{-1} is determined by the stretching vibrations of CH, NH and OH groups [11]. Figure 1b shows the IR absorption spectrum of albumin powder after a 3 min irradiation by the FEL at $\lambda = 130\text{ mkm}$ and with a power of 200 mW . A comparison of these spectra indicates a decrease in the intensities of both the background at 2800 cm^{-1} and the lines of characteristic frequencies at 2930 cm^{-1} . Note that the value of the absorption of the structured spectrum region changes in proportion to the change in the background absorption. Heating the samples by either air convection in a thermostat or the directed stream of hot air from a heat gun with a temperature up to 55°C causes another change in the IR absorption spectra, i.e., the background intensity increases and that of specific bands remains unchanged. Thus, the action of FEL radiation and the thermal heating of OSA samples lead to changes in the IR spectra with different signs. It is concluded then that the nature of changes in absorption spectra is quite different. The difference between the absorption spectra of the starting sample and the irradiated one depends on the time of irradiation (dose).

Fig.1. IR spectra of OSA before (a) and after (b) irradiation.

Both the increase in the intensity of background absorption, determined by cell absorption and sample scattering, and the absence of changes in the intensity in the area of absorption of CH, NH, and OH vibrations under heating can be assigned to either the appearance of fractures in the sample or the subdivision of the granules of laminar OSA. In this case, the background intensity is sure to increase and the intensity of the structured spectrum region will remain constant because the concentration of characteristic groups remains unchanged.

A decrease in the absorption intensity of the background and the structured spectrum region under FEL irradiation can be assigned to the fact that under irradiation a considerable heating causes carbonization, agglomeration, etc. Such “burning” or “agglomeration” can cause a decrease in the number of reflecting surfaces. In addition, the process of “agglomeration” can decrease the number of CH, NH, and OH groups if initial molecules are destructed and the products are formed in which a fraction of molecules containing the given structural fragments is smaller. This chemical process is e.g., well known for the process of humus-formation where chemical transformations in soil cause an increase of C/H, N/C ratios in time. An increase in the values of these ratios testifies to the increase in the aroma of the systems studied [12]. When the process of “burning” prevails in the effect of the decrease of OSA sample absorption, the presence of oxygen will be of major importance because the samples were irradiated from which oxygen was not removed. Therefore, it is interesting to perform experiments on THz irradiation of OSA samples in an oxygen-free medium.

Note that a feasible effect of conglomeration is in agreement with the concepts of the existence of the effect of laser ablation in the system under study. Indeed, since irradiation was performed in a closed volume, the possible products of ablation whose structure is sure to differ from the initial ones, remain in the same volume and can lead to a change in absorption spectra. As for the effect of laser swelling (the swelling of the irradiated sample surface at the irradiation site) which precedes laser ablation, it is also possible because the OSA powder is a set of laminar structures at the surface of which the swelling effect can be observed. However, our method of recording the effects of irradiation fails to reveal the manifestations of swelling because these cause no

changes in the value of absorption of both a substrate and the structured part of the spectrum. Finally, the swelling can be absolutely absent because in our experiments the pulse energy and the dose substantially exceed those in [8].

Fig.2. Electronic absorption spectra of OSA samples before (a) and after (b) irradiation.

Assumption of the effect of “agglomeration” accompanied by a significant chemical destruction of the initial structure of OSA molecule is confirmed by the effect of a decrease in the intensity of the UV spectrum absorption of the OSA molecule after irradiation (fig.2). As follows from the figure, after irradiation, the absorption intensity of the sample decreases by about 40%. This testifies to a decrease in the number of structural groups determining a characteristic “protein” absorption at $\lambda = 270$ nm. The tests performed using the thermally heated OSA samples indicate the absence of any changes in the UV absorption spectra.

Thus, the terahertzian radiation with a wavelength of 130 mkm and a power of 200 mW leads to the observed changes in the UV and IR absorption spectra that are opposite in their directivity to the influence of thermal heating. The changes in absorption spectra are likely to be due to the destruction of initial molecules.

THE ROLE OF THE OPTICAL VISUAL SYSTEM IN RECOGNIZING THE THIRD DIMENSION OF THE OPTICAL IMAGE

Medhat ElMessiery and Manal M. Awad

Department of Engineering Mathematics and Physics Faculty of Engineering
Cairo University, Cairo Egypt

Abstract

Against the popular believe that the acute visual recognition takes place at the fovea this work examines the possible focusing effect of the visual system as a whole in the formation of clear image on the retina as a whole . Accordingly the image is affected by the curvature of the retina, the gradient of the index of refraction of the lens and other media as well as the curvature of the retina itself. The present approach utilizes the ray tracing technique to track the image at different levels until it reaches the curved surface of the retina. The results confirm that it is possible to have a focused image on considerable area of the retina. Also it gives a reasonable explanation to the third dimension recognition.

Introduction

The eye is the most efficient image system. The visual system in man is capable of reducing the dimensions of the external world to almost 0.3 % of its original size without losing acuity, resolution and sharpness of the formed image. It is so adjustable to distance so that it deals with objects that are large and small, far and near and bright and dull. It differentiates colours within the visible spectrum. the system is in a continuous process of adjusting its parameters to focus objects at different distances on the retina (accommodation), thus the refractive power of the lens increases for focusing a near object upon the retina. Most importantly it is capable of recognizing the third dimension of the perceived world.

Over the years, A number of models were introduced in order to explain the remarkable abilities of this system . Most of the classical approaches deal with the paraxial properties of image formation on the retina.

For example, the paraxial schematic eye is highly approximative and serves only in obtaining some parameters such as the equivalent power , the position of the cardinal points, the retinal image size , magnification factor. This model simplifies many mathematical difficulties and overlooks the problems of media inhomogeneity; geometrical considerations and the effect of the curved shape retina on image reception.

Rosenblum et al.¹ introduced a defined model of the human eye by including a inhomogeneous crystalline lens with a purely radial gradient index of refraction. The model has the same basic elements that Blaker² used and consists of a corneal refracting surface with a radius of 7.8 mm, an aqueous chamber that is 3.6 mm thick, and has an index 1.336. The crystalline is composed of an anterior thin lens of radius 10.0 mm with an index of 1.386, a radial gradient of a central index of 1.406 and an edge index of 1.375, and a posterior thin lens of radius 6.0 mm and an index of 1.386.

The index of refraction distribution within the radial gradient takes the form.

$$n(y)=n_0\left(1\pm\frac{V^2}{2}y^2\right)$$

Which describes a quadratic change in refractive index from a central value of n_0 . The magnitude of the coefficient V depicts the type of gradient index lens being used. Rosenblum et al³ used a value for V^2 of 41.58m^{-2} . They found that the focal length, measured from the posterior of the crystalline lens, is 16.55 mm. This posterior focal length compares favourably with the 16.51 mm value that Blaker² obtained using both an axial and a radial gradient in his model of the eye.

Despite the difficulties in introducing a mathematical description to the different refracting surfaces of the system, Al-Ahdali and ElMessiery³ introduced a model of the human eye for which they take into consideration the laminated nature of lens fibres. The thickness of each lamina is 0.0056 mm; thus lens comprises 300 eccentric lenses of minute dimensions. The index gradient of the lens is such that the index of refraction increases exponentially from the lens core to its peripheral zone. The radius of anterior and posterior group decreases exponentially from the pole toward the core.

The laminated lens model offers a plausible explanation to the image formation which is not only compressed but completely focused on a curved surface of the retina. The acuity of the image is usually examined by the spot diagram which is a plot of intersection points of rays from an object point with an image plane. The spot diagram is constructed by using finite ray tracing for all rays that emerge from the object and reach their final destination on the image plane. This diagram is very effectively in studying firstly, the distribution of light intensity on the image plane of a luminous object. Secondly, The imaging features, the possible defects, and limitations of an optical system.

The merit function is related to the image quality. The optimum form of image formation may be achieved by minimizing the merit function. Most commonly used merit functions are the RMS blur circle radius, the wave aberration function, and the sum of squares of the aberration coefficients.

It is based on determination of the central coordinates of the intersection of rays with the image plane. The RMS blur circle radius gives a measure of the transverse aberration among other optical defects of the system. In order to obtain reliable values for RMS blur circle radius, one needs to trace several hundred rays, uniformly distributed over the entrance pupil, through the optical system.

The least square deviation is given as :

$$(\text{RMS})^2 = \frac{1}{N} \sum_{I=1}^N \left[(X(I) - \langle X(I) \rangle)^2 + (Y(I) - \langle Y(I) \rangle)^2 \right]$$

Where $X(I)$ and $Y(I)$ are the coordinates of intersection of the ray at the image plane.

$\langle X(I) \rangle$ and $\langle Y(I) \rangle$ represent the average coordinates of the ray intercepting the image plane.

They are the result of tracing N rays passing through equal areas in the entrance pupil.

$$\langle X(I) \rangle = \frac{1}{N} \sum_{I=1}^N X(I) \quad \text{and} \quad \langle Y(I) \rangle = \frac{1}{N} \sum_{I=1}^N Y(I)$$

Al Ahadali⁴ used caustic surfaces as a merit function and optimized the caustic points towards an Gaussian focal point. In this case the lens parameters are varied by a certain procedure.

Pomerantzeff et al⁵ have introduced an eye model based on the wide angle of light entrance to the eye which was based on finding the square root of the distance between the Gaussian focal point and the caustic Korte and Handelman⁶ discussed the mechanism of eye accommodation and produced a simple model explaining the effect of such accommodation on image formation.

Manal and Essam⁷ have used this model to examine the demagnification power of the eye for near and far vision they found that the image rotates and demagnifies as it formed on the curved retina.

THE MODEL:

Since the dimensions of human eye are large in comparison to the visible wave length ($\lambda = 4000$ to 7000 \AA , Iris diameter = 4 mm), the geometrical optics approach is applicable. In this work we use the laminated lens model, which was described previously and proved its accuracy and reliability in connection with the main parameters of

Figure1, the laminated distribution of the human lens

the visual system. This model is based mainly on the following:

1. The lens is not a homogenous medium, but in fact, there are many zones of optical discontinuity within it and they vary both in refractive index and in radius of curvature as shown in figure(1). In the absence of accurate information about the number of these zones or their curvature. This variation in the index of refraction is dealt with by assuming an exponential increase of the lens index of refraction from the core to the peripheral. The surfaces of both the cornea and the lens deviate from being spherical to ellipsoidal. The lens thickness varies as the lens changes from unaccommodated to the accommodated modes. Accordingly the image is formed with extra features that are it is compressed by an average value from 0.3 to 7 %. The radius of curvature R of the surfaces of the cornea and the lens ; are expressed mathematically as rotationally symmetric aspherical surface so that

$$x^2 + y^2 + (1+Q)z^2 - 2zR = 0$$

The degree of asphericity are examined by varying Q in order to give the optimum acuity of the image on the retina.

2. Vector ray-tracing technique is employed to study the optical characteristics of the system. Both paraxial and marginal rays are simulated, by considering 400 rays (which are equally distributed on the cornea) emerging from each point of the source and they were all traced through the system until they strike the retina. The angles of incidence vary from 0° to $\pm 20^\circ$ and the maximum iris entrance radius was taken as 2mm.
3. Computer simulation technique studied the visual system under accommodation and unaccommodating modes also far and near objects were studied.
4. The constants introduced in this model, were obtained under the optimal conditions of; focusing the images on the curved surface of the retina; Minimum radius of the blur circle and caustic surface and finally minimal spherical aberration.
5. The spot diagram is constructed by using finite ray tracing for all rays that emerge from the object and reach their final destination on the image plane. This diagram is used in studying firstly, the distribution of light intensity on the image plane of a luminous object. Secondly, the imaging features, the possible defects, and limitations of an optical system.

RESULTS:

Figure(2) represents the variations of RMS of the blur radius with lens asphericity for different values of both the cornea Q_c and the lens Q_L . Here, the object is considered at far vision, i.e. the incident rays are parallel to the optical axis and uniformly distributed at the entrance grid placed in front of the cornea.

A four hundred incident rays are used to construct the image of two point objects

(2 mm apart and height 1 mm); as they received on the retina. These objects are considered at far vision. Figures (2a,b,c and d) show the variation of RMS value of the radius of the blur circle of the image point at the retina for different values of cornea asphericity represents; lens asphericity is kept constant at a value of -0.5 . It is clear that the cornea asphericity plays a dominate factor of the image acuity and there is a critical value of Q_C of -1.0 at which the blur circle has a minimum rms radius.

In order to examine the effect of the complicity of the eye in comparison with other optical system the image of a cube in the near vision is first received on a plane Figure(3a) and the second on the curved surface of the retina Figure(3b).

In the first case the projection of the cube is demagnified square that hide the far edges LKMN behind but in the second case the projection of the same object is firstly subjected to different demagnification factor that exhibits the all sides of the cube with different location. Secondly the straight edges are focused and curved and thirdly the image rotates with respect to the object with an angle that is proportional to the axial distance.

Figure (3a) the image formation on a plane

Figure (3b) the image formation on the retina

DISCUSION AND CONCLUSION

The present investigation aimed at producing a complete model to the image formation at the retina of human eye. The model suggests that:

1-The cornea acts as a very powerful converging lens. The aqueous humour has a refractive index differing slightly from the corneal substance, thus the posterior surface has a negligible refractive power. The focusing depends on the cornea curvature of lens surfaces curvature and the gradients of the lens index of refraction. Thus the asphericity of the system plays a strong role in the perfection of the eye as an optical system.

2- There is a linear dependence between corneal asphericity and lens asphericity that gives the optimum sharpness conditions as illustrated in figure(1).

3-The fovea is less than one half a millimetres (less than 500 micrometers) in diameter, which means that maximum visual acuity occurs in only 3 degrees of the visual field. Outside this fovea area the visual acuity is reduced five to tenfold, and it becomes progressively poorer as the periphery is approached.

The image blur circle of a point source could have a rms radius in the order of 5 micrometers. While the average diameter of cones in the fovea (the central part of the retina where vision is most highly developed), is approximately 1.5 micrometers. a person can distinguish two separate points if their centres lie approximately 2 micrometers apart on the retina, which is slightly greater than the width of a single cone in the fovea.

4- The blur circles for objects at far vision do not affect the image. However as the size of the object decreases the image itself as a whole lies within a very small area on the retina (in the order of 2 cones) so that it will not be recognized in full details. For bigger object the resolution improves and the blur circle does not seriously damage the details of the object. As the object comes nearer to the eye the problems of aberration appears more seriously.

6- The demagnification factor for far vision is almost constant ($0.29 \pm 0.003\%$) which means that all images will be demagnified equally irrespective of their geometry as long as they are in the far vision region.

For Near vision (object distance ≤ 25 cm). The demagnification factor is almost constant (6.8) for small object height up to 50 mm. But decreases linearly for object height greater than 50 mm.

Figure (3) comparison between the image formation on a plane and on the curved retina

The variation of lens height is not the main factor affecting the accommodation process but also the shape of the lens (lens asphericity) changes during accommodation in order to obtain the maximum sharpness of the image.

7- The accommodation process does not affect the demagnification factor where it is almost the same for both accommodated and unaccommodated lens. So the accommodation process affects only the sharpness of the image but not the size of the image.

8- The perception of the 3D of the image is not an absolutely mental process. But it is done by the variation of demagnification factor with the axial distance.

CALCULATIONS OF OCULAR HEATING DUE TO COMMUNICATIONS HANDSETS

PETER WAINWRIGHT

HEALTH PROTECTION AGENCY, RADIATION PROTECTION DIVISION,
CHILTON, DIDCOT, OXFORDSHIRE OX11 0RQ, UK

Exposure standards for radiofrequency radiation are framed in terms of acceptable specific energy absorption rate (SAR) in order to limit temperature rises in the body. The eye lens is particularly sensitive due to the lack of perfusion and limited capacity for repair. This work combines the FDTD method (for SAR computations) and finite element method (for thermal computations). A comparison is made between use of an isolated eye model, with convective boundary conditions, and a full head model. The resolution of the model is insufficient to describe the actual blood flow distribution at the choroid. However, an “equivalent perfusion rate” is used which is chosen to match the convective heat transfer coefficient used in other models. Calculations were made for exposure to a wireless handset with a monopole antenna at 380, 900 and 1800MHz, and with a helical antenna at 380MHz. A range of antenna positions was considered. Despite the range of different exposures, a consistent relationship was found between temperature rise in the eye, SAR averaged over the eye, and the 10g average SAR which is subject to restriction in ICNIRP guidelines.

Introduction

Recent years have seen a rapid increase in the use of personal wireless communications devices such as mobile phones. Unlike other sources of radiofrequency and microwave radiation, these are used in close proximity to the head. These sources can produce exposures which approach national or international safety guidelines (ICNIRP 1998, NRPB 2004, IEEE 2005) and therefore require fairly detailed safety assessment.

Over the past few years several authors (van Leeuwen *et al* 1999, Wainwright 2000, Bernardi *et al* 2000, Gandhi *et al* 2001, Hirata and Shiozawa 2003) have computed the temperature rises in the brain expected during use of a GSM mobile phone. In view of the high blood perfusion rate in the brain, temperature rises are likely to remain well within safe limits, indeed considerably less than the normal diurnal variation of brain temperatures.

The eye is more susceptible than most other organs to damage by microwave radiation. It lacks an internal blood supply, so that it is prone to the appearance of hot spots in the central regions (Hirata 2005). Furthermore, the lens has a limited capacity for repair, and the accumulation of cellular debris can lead to a loss of transparency. Animal experiments (Guy *et al* 1975) have shown the induction of cataracts with acute high level exposure.

Many models of the eye, for humans and other species, have been constructed over the years (Legendijk 1982, Scott 1988a,b). Modelling the anatomy of the eye itself is relatively straightforward. However, a critical factor in the temperature calculation is the blood flow in the vessels surrounding the eye, particularly in the choroid, which has a dense network of vessels supplying the retina.

A new combined electromagnetic and thermal model of the human head has been developed at HPA. This model combines a finite difference time domain electromagnetic model with 2mm resolution and a finite element thermal model with 1mm resolution in the eye.

The aim of this study is to clarify the relationship between specific energy absorption rate (SAR) and temperature rises in the eye, and to determine whether the present basic restriction on SAR, recommended by ICNIRP, gives adequate protection against possible adverse effects such as cataract. To this end the new model has been used to compare the SAR and temperature rises due to radiation from antennas and handsets at frequencies produced by several widely used types of communication handset. The three frequencies studied

here are 380MHz (used by the Terrestrial Trunked Radio system, TETRA), 900MHz and 1800MHz (used by GSM mobile phones). The model has also been used to study the differences between two alternative antenna types, the monopole and helix.

Some older studies (Lagendijk 1982, Scott 1988a,b) have used a model of the eye in isolation from the head, and a boundary condition at the surface to take into account all heat losses to blood in the choroid and surroundings. The parameters of this boundary condition were chosen to fit temperature data obtained by measurement in the rabbit eye. In order to transfer this information to the full head model, an “equivalent” blood perfusion rate has been estimated for the layer of elements surrounding the eye. This perfusion rate produces a heat transfer approximately equivalent to that in the older truncated models.

Methods

The SAR in the head was calculated using the finite difference time domain (FDTD) technique implemented by a computer program developed at HPA and previously used to calculate SAR from TETRA exposures (Dimbylow *et al*, 2003). This technique uses a segmented voxel (VOLUME piXEL) dataset to describe the human anatomy. The body is divided into a regular 3D array of hexahedral cells, and the tissue type of each cell is described by an integer code in the range 0 — 255. This tissue code is used as an index into several arrays which contain the electromagnetic and physical properties for each tissue, for example the density, permittivity and conductivity. Each program run is performed for one frequency. Prior to the run, the permittivity and conductivity at that frequency is calculated for each tissue. This is done using a 4-Cole-Cole model (Gabriel 1996). The open boundary was simulated using the “Perfectly Matched Layer” technique (Berenger 1994) using a 6-cell PML layer and a minimum 5-cell air gap between this and the nearest object.

The original voxel dataset of the head was derived from an MRI scan of an adult male. After initial segmentation as described in (Dimbylow and Mann 1994), a number of additional adjustments were made to correct shortcomings in the data acquisition and automatic tissue segmentation. For example, some voxels on the surface of the head had been erroneously labeled as CSF, and some inside the brain labeled as muscle. The original dataset did not distinguish the cartilage in the nose, and the eyes were half-closed. The original dataset did not show the orbital fat between the optic nerve and the orbital muscles; this region appeared as solid muscle.

The resolution of the original voxel dataset was 1 mm. However, in view of the large number of calculations to be performed it was found that a lower resolution of 2 mm was more appropriate for the majority of SAR calculations. Therefore, the dataset was resampled to the lower resolution using a simple voting algorithm to determine which of the 8 voxel tissue types would be assigned to the larger cube. In the course of this procedure the thin layer of skin covering the head was eroded in places. A subsequent automated procedure ensured a uniform 2 mm (1 voxel) covering of skin over the entire head.

For the thermal calculations a finite element technique was used, since this allows for non-uniform meshing and better conformance to curved interfaces (such as the surface of the eyeball). In this case accuracy of anatomical modeling far from the source is not critical, while the structures of the eye must be represented in detail. The finite element mesh was derived by an automated procedure (Wainwright 1999) from the voxel dataset used for the SAR calculations. The SAR from the FDTD code was interpolated onto the finite element mesh in the following way: If an element lay entirely within one voxel, the SAR for that voxel was assigned to the element. If an element spanned several voxels, a simple numerical quadrature procedure was applied to integrate the power density over the element and derive the equivalent SAR.

The heat flow was modeled using the bioheat equation (Pennes 1948):

$$\rho c \frac{\partial T}{\partial t} = \nabla \cdot (k \nabla T) + \rho S - \rho \rho_b c_b \omega (T - T_b) \quad (1)$$

together with the boundary conditions

$$k \frac{\partial T}{\partial n} = -(h_r + h_c)(T - T_{amb}) \quad (2)$$

where ρ , c , k and ω are respectively the density, specific heat, thermal conductivity and blood perfusion rate, T is the temperature and S the SAR. The suffices “b” and “amb” indicate the parameters of blood and the ambient temperature. The radiative and convective heat transfer coefficients h_r and h_c may vary over the surface of the body. However, in this work it has been assumed that the total value h is 20 W kg⁻¹ for the cornea (Lagendijk 1982) and 8 W kg⁻¹ elsewhere. In this paper all results are shown for the steady state, $\partial T / \partial t = 0$.

Choroidal blood flow

Although a very thin layer, the choroid has a particularly high blood perfusion rate, which is necessary to supply the oxygen demands of the retina. This has a significant impact on the temperature distribution in the posterior chamber of the eye. The actual value and distribution of choroidal blood flow in humans is still a matter of debate. Many papers have used a model of the eye in isolation from the head, and a boundary condition at the surface to take into account all heat losses to blood in the choroid and surroundings (Lagendijk 1982, Scott 1988a,b). More recently, the value of the heat transfer coefficient has been questioned. It is not clear whether the extrapolation from rabbit to human models is valid. The anesthesia used in the original study may have had a significant effect on the measured blood flow (Kojima *et al* 2004).

Despite these shortcomings, the isolated eye models have been widely used, and a definitive improvement on this approach has not yet been forthcoming. Therefore the model in this study has been designed to replicate as closely as possible the effect of the choroid in the older models, while adding a complete model of the head. By examining simple analytical models of planar layers or concentric spheres it is possible to derive an “equivalent perfusion” for the choroid which replicates the heat loss of the older models in the simplest cases. This is then applied to the realistic SAR distribution in the whole head model.

First consider the steady-state one-dimensional bioheat transfer problem with two regions: region 1 the “choroid” ($0 < x < d$), and region 2 the “head” ($x > d$). Assume a known heat flux F incident from the left at the interface $x=0$. In each region the temperature rise ΔT can be expressed as a sum of exponentials:

$$\Delta T(x) = A_i \exp(\alpha_i x) + B_i \exp(-\alpha_i x) \quad (3)$$

where in each region $i=1,2$

$$\alpha_i = \sqrt{\frac{\rho_b c_b \rho_i \omega_i}{k_i}} \quad (4)$$

The coefficients A_i and B_i can then be obtained using the continuity of temperature and heat flux at the tissue interfaces. Note that in the “infinite” region $x > d$ the solution cannot have an exponentially increasing part, so it is necessary that $A_2=0$. When this is done, we have a relationship between heat flux F and $\Delta T(0)$:

$$h = \frac{F}{\Delta T(0)} = k_1 \alpha_1 \frac{k_1 \alpha_1 \sinh(\alpha_1 d) + k_2 \alpha_2 \cosh(\alpha_1 d)}{k_1 \alpha_1 \cosh(\alpha_1 d) + k_2 \alpha_2 \sinh(\alpha_1 d)} \quad (5)$$

Assume the rest of the “head” contains tissue of very low perfusion, so $\alpha_2 \approx 0$. Then in order to generate a heat transfer coefficient of $h=65 \text{ W m}^{-1} \text{ }^\circ\text{C}^{-1}$ (Lagendijk 1982) it is necessary to set $\alpha_1=341 \text{ m}^{-1}$, or $\omega_1=16.3 \text{ ml kg}^{-1} \text{ s}^{-1}$. If the “head” contains tissue similar to fat, $\omega_2=0.467 \text{ ml kg}^{-1} \text{ s}^{-1}$ (Duck 1990, Appendix A). Then α_1 must have a somewhat smaller value of 284 m^{-1} .

It is possible to derive a similar analytical solution for a more realistic spherical model of the eye, where the “eye” is the region $r < a$ and the “choroid” is $a < r < a+d$. In this case

$$h = \frac{k_1}{a} \frac{(k_1 \alpha_1^2 a + k_2 \alpha_2) \sinh(\alpha_1 d) + (k_2 \alpha_1 \alpha_2 a + k_1 \alpha_1) \cosh(\alpha_1 d)}{k_1 \alpha_1 \cosh(\alpha_1 d) + k_2 \alpha_2 \sinh(\alpha_1 d)} \quad (6)$$

Interestingly, the change from planar to spherical geometry has a major effect on the heat transfer coefficient. For an eye of radius 1.25 cm surrounded by fat, this predicts $h=67 \text{ W m}^{-1} \text{ }^\circ\text{C}^{-1}$ even when $\alpha_1=0$. This means that the coefficient proposed by Lagendijk (1982), $65 \text{ W m}^{-1} \text{ }^\circ\text{C}^{-1}$, could be entirely accounted for by a sufficiently large volume of relatively low-perfusion material surrounding the eye. Since the surroundings include higher-perfusion tissues such as muscle and brain, and the choroid itself, it seems likely that the true value of the effective h is considerably higher than this.

As a control value, this paper uses a blood perfusion rate of $16.3 \text{ ml kg}^{-1} \text{ s}^{-1}$ in the choroid. Using the simple spherical model in Equation (6), this corresponds to $h=130 \text{ W m}^{-1} \text{ }^\circ\text{C}^{-1}$, a value which is twice that used in Lagendijk’s rabbit model. The sensitivity of the results to this parameter has been investigated by either doubling, or eliminating entirely, the blood flow to the choroid.

Results

First, several computations were made to validate different aspects of the method. The basic configuration was a monopole, radiating at 380 MHz, on top of a metal box. This is a simplified representation of the Motorola MTP700 TETRA handset (Dimbylow *et al* 2003). As a worst-case scenario the handset model was placed as close as possible to the eye in a vertical orientation.

There was some concern initially that the 5-cell (1cm) air gap between the objects and the PML layer might not be sufficient for adequate accuracy in the FDTD calculations. Therefore one typical calculation was performed with both a 5-cell and a 10-cell gap. However, the resulting change in the computed SAR averages was found to be less than 1%. It was therefore concluded that the 5-cell gap was indeed adequate for the present study.

Some comparisons were done to investigate the effect of the improvements made to the segmentation of the anatomical model. The original model contained muscle in place of the cartilage of the nose and the orbital fat behind the eyeball. Inserting the orbital fat had relatively little impact. The maximum change in temperature was

Figure 1: Finite element and exact solution for temperature in a sphere

about 10% of the peak temperature rise in the eye. A similar result was found for the cartilage.

The finite element thermal method was validated by comparison with the exact solutions derived by Durkee *et al* (1990) for spherical shell models. A uniform SAR of 1 W kg^{-1} was injected into a homogeneous sphere of muscle-equivalent material with a radius of 5 cm. The arterial blood temperature was 37°C , the ambient temperature was 20°C and the convective heat transfer coefficient h at the surface was $8 \text{ W m}^{-1} \text{ }^\circ\text{C}^{-1}$. Several finite element meshes were created to model this sphere. These meshes each had a nominal resolution of 2 mm. However, one (the “conforming mesh”) was chosen to conform as closely as possible to the spherical boundary. The others were created by the automeshing procedure (Wainwright 1999) and by simply subdividing a mesh of cubical voxels. The latter meshes do not have a continuous normal vector at the surface, and as a result the surface area is somewhat greater than that of the real sphere. This causes a slight overestimate of heat loss from the surface, and slightly lower predicted temperatures as seen in .

A range of different thermal models were compared, ranging from a simple analytic solution with a spherical “eye”, to a finite-element solution in an anatomically realistic head. This comparison shows the effects of the factors which are included at each stage of development of a realistic model. The differences between each model and the next can be explained, and this provides some reassurance that the final finite-element calculation correctly implements the model. Each model was applied to a test case consisting of a uniform SAR, 1 W kg^{-1} , applied within the eye alone. For each model, the maximum and minimum ΔT within the eyeball was calculated. The maximum occurs at or near the centre of the eyeball, and the minimum at the periphery.

The successive models were:

1. A homogeneous spherical “eye”, of 26mm diameter. A constant convective heat transfer coefficient $h=65 \text{ W m}^{-2} \text{ }^\circ\text{C}^{-1}$ was assumed at the surface (Lagendijk 1982). This model was solved using the analytic method (Durkee *et al* 1990).
2. A finite element model containing the eye tissues only, extracted from the full head model, with the same constant h .
3. The same model as in 2, but using a different coefficient $h=20 \text{ W m}^{-2} \text{ }^\circ\text{C}^{-1}$ on the cornea (Lagendijk 1982).
4. The complete head model, with SAR in the eye alone, with no special blood supply to the choroid.

5. The complete head model, with SAR in the eye alone, using the equivalent choroidal blood flow suggested above.

The results are shown in Table 1.

	<i>Min. ΔT</i> (°C)	<i>Max. ΔT</i> (°C)
1. Spherical	0.067	0.114
2. Isolated eye, constant h	0.046	0.110
3. Isolated eye, variable h	0.060	0.135
4. Eye in head	0.063	0.137
5. Eye in head, choroidal BF	0.031	0.102

Table 1: Comparison of eye models

Good agreement is seen between the maximum temperature rise in models 1 and 2. Errors are due to the finite element discretization, as discussed above. The greatest discrepancy arises in those areas of the eye surface where the staircasing effect is most noticeable. The difference between models 2 and 3 arises from the reduction of the heat transfer coefficient at the cornea. The temperature profile is now asymmetric, with the maximum being located toward the anterior part of the eye.

The agreement between models 3 and 4 is at first sight the most surprising feature of these calculations, because model 4 contains no special blood supply for the choroid. However, this result does agree with the argument made in the previous section. There it was shown that the fatty tissue surrounding the eye has a sufficient blood flow to generate an effective heat transfer coefficient of $67 \text{ W m}^{-1} \text{ }^{\circ}\text{C}^{-1}$, nearly equal to the value used in the isolated eye models. Figure 2 shows the maximum and minimum ΔT in the eye for a range of choroidal blood perfusion. The central value, in particular, is relatively insensitive to this value. The difference between the central and peripheral temperature is almost constant because there is a constant thermal resistance between the centre and periphery; this cannot be eliminated however large the choroidal perfusion.

Figure 2: Effect of choroidal perfusion on ΔT

Figure 3 shows the TETRA handset placed as close as possible to the eye; the antenna feed point is 2.4 cm from the surface of the eye. Only the metallic parts of the antenna and handset are shown here. The handset is covered with a plastic casing and this prevents it from being moved any closer to the eye. In the following figures, this position is used as the origin for displacements of the antenna. The length of the monopole is about $3\lambda/16$, where λ is the free-space wavelength. As seen from the figures this leads to quite a long and unwieldy antenna at the TETRA frequency, 380MHz. A more compact design uses a helical antenna (Dimbylow *et al* 2003). The temperature and SAR quoted here have been calculated for an antenna input power normalized to 1W. In order to study the effect of frequency on the temperature distribution, calculations were also performed using appropriately scaled monopole antennas at the GSM frequencies, 900 and 1800MHz, mounted on the same metal box.

Figure 4 and Figure 5 show the relative SAR profiles for the TETRA monopole handset located at 2.4 cm and at

8.4 cm. The greyscale values are not to the same scale. In Figure 4 the maximum (white) represents 4 W kg^{-1} , while in Figure 5 it represents 1 W kg^{-1} . It can be seen here that when the handset is held well away from the face the maximum SAR occurs not in the eye but in superficial structures such as the nose. Also, for a distant source, the SAR distribution in the eye becomes much more uniform, since the penetration depth at 380MHz is comparable to the eye size.

Figure 3: TETRA handset close to eye

Figure 4: TETRA at 2.4cm

Figure 5: TETRA at 8.4cm

An investigation was made into the relative contributions made to the temperature rise by the SAR inside and outside the eye. A plot of temperature rise along the central AP axis of the eye (Figure 6) shows heat conduction from outside the eyeball accounts for about 40% of the temperature rise in the lens. A detailed examination of the SAR and temperature profiles (not shown) has been done and reveals that this heat comes mainly from the orbital muscles above and below the eye.

Figure 7 shows the temperature rise along the central axis of the eye for various values of the choroidal perfusion rate. The middle curve is for the control value; the other curves show ΔT for the case of no perfusion or of double perfusion. As previously seen in Figure 2, it is apparent that increments in the perfusion rate become successively less effective, and in fact that ΔT for the lens converges to a nonzero value.

Figure 8 shows the central axis temperature rises for TETRA monopole and helical antennas, and GSM900 and GSM1800 monopole antennas (with appropriately scaled size) mounted on the same metal box. The profiles are very similar. The main difference arises from the fact that the penetration depth is smaller at 1800MHz, and therefore in this case the temperature rise is noticeably more peaked in the anterior part of the eye.

Table 2 summarises the SAR averages and temperature rises obtained for three frequencies, two antenna types and two values of the antenna-eye distance. The ICNIRP basic restriction (ICNIRP 1998) is framed in terms of the maximum SAR average over any 10g of tissue in the head. However, also listed is the average over the eye alone, which has been calculated by other authors (Hirata 2005). The maximum ΔT is always found near the posterior pole of the lens. For sufficiently small values of SAR and ΔT , thermoregulatory changes to blood flow are negligible and the relationship between these quantities is therefore linear. The slope of this linear curve is

also shown in the table, using both the ICNIRP SAR average and the eye averaged SAR.

Figure 6: Contribution of internal and external SAR to ΔT

Figure 8: Temperature rises for various antenna types and frequencies

	SAR_{eye} ($W\ kg^{-1}$, ~10g)	SAR_{head} ($W\ kg^{-1}$, 10g)	$Max.\ \Delta T(eye)$ ($^{\circ}C$)	$\frac{\Delta T}{SAR_{eye}}$	$\frac{\Delta T}{SAR_{head}}$
Monopole, 380MHz, 24mm	1.73	2.95	0.33	0.19	0.11
Monopole, 380MHz, 84mm	0.42	0.85	0.077	0.18	0.09
Helix, 380MHz, 24mm	2.35	3.97	0.44	0.19	0.11
Helix, 380MHz, 84mm	0.51	1.04	0.09	0.18	0.09
Monopole, 900MHz, 24mm	1.65	2.71	0.31	0.19	0.11
Monopole, 900MHz, 84mm	0.09	0.55	0.017	0.18	0.03
Monopole, 1800MHz, 24mm	2.97	4.00	0.55	0.19	0.14
Monopole, 1800MHz, 84mm	0.24	0.70	0.043	0.18	0.06

Table 2: Temperature rise and SAR summary

When the eye-averaged SAR is $10W\ kg^{-1}$, the temperature rise in the eye is generally greater than $1^{\circ}C$ but less than $2^{\circ}C$. However, when the ICNIRP occupational exposure restriction is respected ($10W\ kg^{-1}$ in the head), the temperature rise in the eye is limited to about $1^{\circ}C$ for all the TETRA exposures. However, it might reach $1.4^{\circ}C$ if an antenna at 1800MHz were held very close to the eye.

Summary

These calculations have shown that the temperature rise in the eye is due not only to the energy directly absorbed by the eye tissues, but also by heat conduction from adjacent tissues which also absorb significant energy from the electromagnetic field. In some cases, about 40% of the temperature rise in the lens can be attributed to conduction from tissues outside the eye. Some studies have cited the SAR average over the eye as a predictor of thermal effect. This is because the mass of the eye is similar to the 10g averaging mass specified by ICNIRP. However, the present results show that the absorption in the orbital muscles must also be taken into account.

Under most circumstances the SAR average over the eye is substantially lower than the maximum SAR average in the head. Then, if the ICNIRP occupational exposure restriction is followed ($10W\ kg^{-1}$ in the head), the temperature rise in the eye is generally less than about $1^{\circ}C$. However, at 1800MHz, it is theoretically possible to place an antenna very close to the eye and to produce larger temperature rises in the anterior part of the eye. However, this is still below the threshold which has been determined for cataractogenesis under acute exposures.

Abstract

Hodgkin-Huxley model, describing generation of action potentials in the nerve cell membranes has been used for appreciation of the possible EMF influence mechanisms on the brain own electric activity. The carried calculations have shown that at simultaneous passing through a nerve cell of action potentials and external ac, suppression of the own excitation pulses is possible starting from the certain level of the external current value, which depends on its frequency. To avoid such suppression of action potentials, their levels may be increased relatively minimum limit level. It may be supposed that brain "tunes up" its work at presence of external ac, increasing amplitudes of its own excitation signals so that their suppression does not occur. It is possible also that this "tuning" acts some time after external EMF removing while brain adapts again to its absence, as it is observed in experiment.

1. Introduction.

There are studies connected with influence of electromagnetic fields (EMF) on the activity of cerebrum of animals (see for instance [1]) and people (see for instance [2-5]). As it is shown in these works, low frequency or amplitude modulated radio-frequency EMF of the defined strength and frequency may influence bioelectrical activity of mammals' cerebrum. It is expressed in changes observed by means of electroencephalography (EEG) [1-5]. However, literature data on the character of the EMF influence are discrepant. Thus, it is mentioned about blocking of cerebrum bioelectrical activity upon action of magnetic field with 10 Hz frequency and 0.1 mTл stress [4]. At the same time it is shown in [2] that influence of the magnetic field with frequency $f=0-500$ Hz and 0.2 mTл magnetic field stress was expressed in increase of the potential levels, registered by EEG after lifting of the exposure. It is shown in [3] that magnetic fields of 60 Hz frequency and 1 Ga stress cause reliable change of EEG of people after lifting of the exposure.

As it is shown in [6], heterogeneity of the electrical properties of cortex tissues and, in particular presence of the intercellular fluid, leads to low frequency filtration of electromagnetic field. As a result, EEG has only low frequency components. It is possible that the answer of the cerebrum neurons to the influence of radio-frequency electromagnetic fields is suppressed also by the low frequency filter, which serves cerebrum intercellular fluid, so it is not registered by EEG. However, influence on the people's EEG of high frequency electromagnetic fields in the limited time diapason $t < 300$ ms after lifting of the exposure has been fixed [5].

The purpose of this work is estimation of the parameters of electrical processes in the membrane of a brain neuron for evaluation of the limit levels of current density, induced as a result of external EMF application, which do not influence own bioelectric processes, occurring at normal cortex operation in absence of an external EMF. To understand the mechanism of EMF influence on the own electrical activity of cerebrum, it is suggested to use simple, but demonstrative Hodgkin-Huxley model [7], describing passage of bioelectric pulses through the neuron membrane.

2. Evaluation of the neuron membrane charges and potentials at external current flow.

Let's consider influence of the external EMF on the cellular level. The author of [8] has made estimation of Q_R – charge density of the cell membrane: $Q_R = V_m \cdot C_m$, where $C_m = 10^{-2} \text{ F/m}^2$ – specific membrane capacitance, $V_m = -60 \text{ mV}$ – resting potential of the membrane: $Q_R \sim 6 \cdot 10^{-4} \text{ K/m}^2$. Let's evaluate Q_p – value of the charge density in brain tissues at flowing in them of the normalized, for instance in [9], permitted level of current density $J_p = 10 \text{ mA/m}^2$ at $f \leq 1000 \text{ Hz}$: $|Q_p| = |J_p| / \omega$. For industrial frequency 50 Hz $|Q_p| \sim 0.3 \cdot 10^{-4} \text{ K/m}^2$, i.e. makes up about 5 % from Q_R . For lower frequencies, for instance 10 Hz , as in the experiments described in [1,2], $|Q_p|$ is even greater: $|Q_p| \sim 0.16 \cdot 10^{-3} \text{ K/m}^2$, i.e. makes up nearly 27 % from Q_R . Such a change of charge may influence own electrical processes, occurring at cerebrum functioning.

Let's perform evaluative calculations of the levels of potential, appearing in intercellular medium and membrane of a nervous cell at flowing in the cerebrum tissues of the very low frequency ($f \leq 1000 \text{ Hz}$) current with the density $J^{\text{ext}} = 10 \text{ mA/m}^2$, equal to the permitted level. It is necessary to take into account that an external current J^{ext} passes both through the membrane and through the nucleus of the cell. Let's consider that specific conductivity of the intercellular fluid does not exceed $\gamma_i \sim 0,03 - 0,1 \text{ C/M}$ at frequencies $f \leq 100 \text{ Hz}$ (see for instance [10]). Then G_i^* – conductivity of the intercellular medium corresponding to the unit area, makes up: $G_i^* = G_i / S = \gamma_i \cdot S / (L \cdot S) \sim 10^4 \text{ S/m}^2$ (at $L \sim 10^{-5} \text{ m}$ – transverse size of a cell, S – the area of a cell). At the same time, capacitive conductivity of a membrane, corresponding to a unit area at frequency, for instance 10 Hz , is equal to: $\omega \cdot C_m^* = \omega \cdot C_m / S \sim 0,6 \text{ S/m}^2$. So, at outside current J^{ext} flowing, Ohm's law for a cell membrane and intercellular medium may be expressed as follows, taking into account that $G_i^* \gg \omega \cdot C_m^*$:

$$U = I^{\text{ext}} \cdot [1/(\omega \cdot C_m) + 1/G_i] = I^{\text{ext}} \cdot S \cdot [1/(\omega \cdot C_m \cdot S) + 1/(G_i \cdot S)] = J^{\text{ext}} \cdot [1/(\omega \cdot C_m^*) + 1/G_i^*] \sim J^{\text{ext}} / (\omega \cdot C_m^*) \sim 16 \text{ mB},$$

where I^{ext} – external current.

Thus, at very low frequencies of the external current flowing through a cell, the main drop of voltage is in its membrane (see [8] also). So, at flowing of the induced by external sources current with density 10 mA/m^2 , which is normalized as permitted, drop of voltage in a membrane may reach 16 mV at $f = 10 \text{ Hz}$ and about 3 mV at $f = 50 \text{ Hz}$.

The same result may be obtained at evaluation of the field problem. In 1D approach: $J_i = J_m = J^{\text{ext}}$ (where J_i – current density in the intercellular medium; J_m – current density in the cell membrane) and $J_i = \gamma_i \cdot E_i$; $J_m = j \cdot \omega \cdot \varepsilon \cdot \varepsilon_0 \cdot E_m$ (where E_i – electric field stress in the intercellular medium, E_m – electric field stress in the cell membrane, $\varepsilon = 81$). From this $\gamma \cdot |E_i| = \varepsilon \cdot \varepsilon_0 \cdot \omega \cdot |E_m|$. For very low frequencies $E_m \gg E_i$, thus for $f = 10 \text{ Hz}$ and $\gamma_i = 0.1 \text{ S/m}$:

$$E_m = |E_i| \cdot [\gamma_i / (\varepsilon \cdot \varepsilon_0 \cdot \omega)] \sim |E_i| \cdot 0.2 \cdot 10^7. \quad (1)$$

General fall of voltage in a cell:

$$U_c = d_m \cdot |E_m| + d_i \cdot |E_i|, \quad (2)$$

where d_i – thickness of a cell ($d_i \sim 10^{-5} \text{ m}$); d_m – membrane thickness ($d_m \sim 10^{-8} \text{ m}$).

Substituting (1) in (2), we get: $U_c = |E_m| \cdot (10^{-8} + 10^{-5} \cdot 5 \cdot 10^{-7})$, thence $E_m \cdot d_m \sim U_c$. As a result we get:

$$U_m \sim U_c \sim [J^{\text{ext}} / (\varepsilon \cdot \varepsilon_0 \cdot \omega)] \cdot d_m,$$

where U_m – voltage drop in a membrane,

that at $f = 10 \text{ Hz}$ gives $U_m \sim 16 \text{ mV}$.

Considering that this value has the same order as, for instance potential difference, caused by the presence of K^+ ions inside a cell, $E_K \sim -12 \text{ mV}$ (see for instance [11]), such change of the membrane potential may cause change of its conductivity to K^+ ions.

3. Calculations with the help of Hodgkin-Huxley model.

Let's use the known Hodgkin-Huxley model [7] describing electric processes in the membrane of neuron (see fig. 1). The equivalent electrical circuit of a patch of the axon membrane is shown in fig. 2.

Fig. 1. A real neuron.

Fig. 2. Equivalent electrical circuit of a patch of axon.

It is known that high concentration of potassium ions as well as low concentration of sodium and chlorine ions exists inside a neuron cell in the state of rest. The membrane of a cell performs the role of a barrier, preventing ions penetration from the intercellular medium inside a cell and vice versa. The rest potential E_m settles in a cell membrane as a consequence of presence on its both sides of different concentration of Na^+ and K^+ ions. If it is considered that membrane potential V is equal to 0 in the rest state, $E_K \sim -12$ mV, $E_{Na} \sim 115$ mV, $E_{rest} \sim 10.613$ mV, $G_m \sim 3$ Sm/m², $C_m \sim 10^{-2}$ F/m (see for instance [11]), where E_K - potential difference, connected with presence of potassium ions inside a cell; E_{Na} - potential difference, connected with presence of sodium ions inside a cell; E_{rest} - value, chosen by calculations, which provides equality to zero of the membrane

NUMERICAL EVALUATION OF EXTERNAL ELECTROMAGNETIC FIELDS

potential in the rest mode; G_K - conductivity of a unit area to K^+ ions; G_{Na} - conductivity of a unit area to Na^+ ions; G_m - leak conductivity of a unit area; C_m - membrane capacity of a unit area (see fig. 2).

Let's take into account presence in the equivalent circuit of a cell of the additional current sources, imitating current of axon excitation, as well as current, running in cortex at application of an external EMF. As all quantities in the equivalent scheme are expressed as specific values, we suppose that external source is characterized by density J^{ext} and frequency f , and the source of axon excitation current is characterized by density J^{ax} and duration τ^{ax} .

It is supposed in Hodgkin-Huxley model that full current through a membrane consists of a capacitive current, as well as conductivity currents of K^+ , Na^+ ions and leak current through active resistance of a membrane. Nonlinear dependencies of the conductivities to K^+ and Na^+ ions relatively the value of the membrane voltage V are entered in this model. These dependencies assume that transition from non-conducting state of a membrane to its conducting state occurs at certain voltage on the membrane. According to Hodgkin-Huxley model, this transition complies with the first-order kinetics. The equation of such transition for K^+ ions may be written down as follows:

$$\frac{dn}{dt} = \phi(T) \cdot [\alpha_n(V) \cdot (1 - n) - \beta_n(V) \cdot n], \quad (3)$$

where $\phi(t) = 3^{(T-6.3)/10}$ - coefficient depending on the temperature; T - temperature in the Celsius degrees; $\alpha_n(V)$, $\beta_n(V)$ - coefficients depending on the voltage level.

Specific conductivity to potassium ions G_K is supposed to be equal to $G_K = \bar{G}_K \cdot n^4$ ($\bar{G}_K = 36 \text{ mS/cm}^2$), and coefficients $\alpha_n(V)$, $\beta_n(V)$ are written as follows:

$$\alpha_n(V) = \frac{10 - V}{100 \cdot \{\exp[(10 - V)/10] - 1\}}; \quad \beta_n(V) = 0.125 \cdot \exp(-V/80),$$

where V - in millivolt.

Specific conductivity to sodium ions G_{Na} is written in the form $G_{Na} = \bar{G}_{Na} \cdot m^3 \cdot h$ ($\bar{G}_{Na} = 120 \text{ mS/cm}^2$), and it is supposed also that transition from m condition to $(m-1)$ condition and from h to $(h-1)$ condition also complies with the first-order kinetics:

$$\frac{dm}{dt} = \phi(T) \cdot [\alpha_m(V) \cdot (1 - m) - \beta_m(V) \cdot m]; \quad (4)$$

$$\frac{dh}{dt} = \phi(T) \cdot [\alpha_h(V) \cdot (1 - h) - \beta_h(V) \cdot h], \quad (5)$$

where $\alpha_m(V)$, $\beta_m(V)$, $\alpha_h(V)$, $\beta_h(V)$ - coefficients depending on the voltage level.

Coefficients $\alpha_m(V)$, $\beta_m(V)$, $\alpha_h(V)$, $\beta_h(V)$ are written as follows:

$$\alpha_m(V) = \frac{25 - V}{10 \cdot \{\exp[(25 - V)/10] - 1\}}; \quad \beta_m(V) = 4 \cdot \exp(-V/18);$$

$$\alpha_h(V) = 0.07 \cdot \exp(-V/20); \quad \beta_h(V) = \frac{1}{\exp[(30 - V)/10] + 1},$$

where V - in millivolt.

Let's write down the equation for all current densities, flowing through a membrane (equivalent scheme is shown in fig. 2):

$$C_m \cdot \frac{dV}{dt} = \bar{G}_{Na} \cdot m^3 \cdot h \cdot (E_{Na} - V) + \bar{G}_K \cdot n^4 \cdot (E_K - V) + G_m \cdot (V_{rest} - V) + J^{ext} + J^{ax}. \quad (6)$$

Let's replace derivatives in the expressions (3)-(6) by their differential analogues and express volumes of the sought functions at the time step t for $T=6.3^0$ C as follows:

$$n_t = \frac{n_{t-\Delta t} + \alpha_n(V_t) \cdot \Delta t}{1 + \Delta t \cdot [\alpha_n(V_t) + \beta_n(V_t)]}; \quad m_t = \frac{m_{t-\Delta t} + \alpha_m(V_t) \cdot \Delta t}{1 + \Delta t \cdot [\alpha_m(V_t) + \beta_m(V_t)]};$$

$$h_t = \frac{h_{t-\Delta t} + \alpha_h(V_t) \cdot \Delta t}{1 + \Delta t \cdot [\alpha_h(V_t) + \beta_h(V_t)]}; \quad V_t = \frac{V_{t-\Delta t} \cdot C_m / \Delta t + \bar{G}_{Na} \cdot m^3 \cdot h \cdot E_{Na} + \bar{G}_K \cdot n^4 \cdot E_K + G_m \cdot V_{rest} + J^{ext}(t) + J^{ax}}{C_m / \Delta t + \bar{G}_{Na} \cdot m^3 \cdot h + \bar{G}_K \cdot n^4 + G_m},$$

where Δt [ms] - step in time domain; C_m [$\mu F/cm^2$]; J^{ext} , J^{ax} [$\mu A/cm^2$]; \bar{G}_K , \bar{G}_{Na} [mS/cm²]; V [mV].

The obtained system of nonlinear equations was solved by the iterative method in each time step. The value of Δt was chosen equal to 0.01 ms.

An example of the calculated axon membrane voltage at application to it of the excitation current with density $J_{min}^{ax} = 14 \mu A/cm^2$ and duration $\tau^{ax} = 0.5$ ms is shown in fig. 3.

Fig. 3.

The calculated dependencies of n , m , h change in time domain for this case are presented in fig. 4.

Fig. 4.

NUMERICAL EVALUATION OF EXTERNAL ELECTROMAGNETIC FIELDS

It is known that excitation potentials with certain periodicity are generated in an axon at application of an external dc. The same phenomenon is present also at application of an external ac. The calculated boundary levels of the external currents densities J_{lim1}^{ext} and J_{lim2}^{ext} , such that presence of an external field does not cause appearance of induced excitation potentials in an axon if $J^{ext} < J_{lim1}^{ext}$, but potentials with certain periodicity depending on J^{ext} value are generated in an axon if $J^{ext} > J_{lim2}^{ext}$ are presented in the table for different frequencies. Generation of a single induced excitation pulse or a transition stage occurs at $J_{lim1}^{ext} < J^{ext} < J_{lim2}^{ext}$.

Table.

f [Hz]	J_{lim1}^{ext} [mA/m ²]	J_{lim2}^{ext} [mA/m ²]
10	50	60
30	20	25
50	15	20
100	20	30
1000	65	70

Calculated changes in time domain of the potentials in the neuron's membrane at application of the external current of 10 Hz frequency with the amplitude 60 mA/m² and 100 mA/m² are presented in fig. 5 and 6 correspondingly.

Fig. 5. Dependence of the axon membrane voltage from time at flowing of the external current with frequency 10 Hz and amplitude 60 mA/m².

Fig. 6. Dependence of the axon membrane voltage from time at flowing of the external current with frequency 10 Hz and amplitude 100 mA/m².

As carried calculations have shown, at simultaneous passage through an axon of an external current J^{ext} , as well as axon excitation current J^{ax} , starting from the defined level of an external current, depending on its frequency, suppression of the excitation pulses occurs if they pass through the axon membrane during negative half-waves of external current (see fig. 7 moment t_1). The same external current does not affect excitation pulses if they appear during positive half-waves (see fig. 7 moment t_2). The carried calculations have shown that current caused by the presence of external field ceases to suppress brain own excitation pulses only when $J^{\text{ext}} < J^{\text{ext}}_{\text{lim0}}$ (where $J^{\text{ext}}_{\text{lim0}}$ - limit level of current density). For the industrial frequency of 50 Hz this limit level is equal to: $J^{\text{ext}}_{\text{lim0}} = 1.5 \text{ mA/m}^2$, for other frequencies it should be calculated.

Fig. 7. Dependence of the axon membrane voltage from time at flowing of the external current with frequency 50 Hz and amplitude 10 mA/m^2 and simultaneous flowing of excitation pulses of amplitude $J^{\text{ext}} = 14 \text{ } \mu\text{A/cm}^2$ in the moments t_1, t_2 .

It was obtained from the calculations also that to prevent suppression of brain own excitation pulses by the external current of permitted density $J^{\text{ext}} = 10 \text{ mA/m}^2$, their levels should be increased up to $J^{\text{ax}} = 18 \text{ } \mu\text{A/cm}^2$ - approximately on 30 % relatively the minimum limiting level of $J^{\text{ax}}_{\text{min}} = 14 \text{ } \mu\text{A/cm}^2$ at which excitation pulses of duration $\tau^{\text{ax}} = 0.5 \text{ ms}$ still pass (see fig.8).

Fig. 8. Dependence of the axon membrane voltage from time at flowing of the external current with frequency 50 Hz and amplitude 10 mA/m^2 and simultaneous flowing of excitation pulses of amplitude $J^{\text{ext}} = 18 \text{ } \mu\text{A/cm}^2$ in the moments t_1, t_2 .

From certain level of external current density, full suppression of the own brain electrical activity has been observed in the calculations. It may be a cause of the analgesic effect during application of the external low frequency EMF due to blocking of action potential propagation.

Thus, from an example of simple calculations, it may be seen that at certain conditions of irradiation, flowing through the membrane of axon of the low frequency external ac can cause suppression of the own excitation signals passing through the membrane. It can cause also generation of the induced excitation signals, as well as increase of the levels of brain own excitation potentials so that they would not be suppressed by the presence of external current, i.e. all phenomena observed in experiment (see [1-5]).

Conclusions.

1. As calculations with the help of Hodgkin-Huxley model have shown, flowing through nervous cells of current with density 10 mA/m^2 and frequency $f < 100 \text{ Hz}$ in absence of own brain excitation pulses does not cause appearance of the induced excitation potentials. However, simultaneous flowing through an axon of the external very low frequency current $J_{\text{lim}0}^{\text{ext}} < J^{\text{ext}} \leq 10 \text{ mA/m}^2$ and excitation pulses can cause suppression of the excitation pulses, moreover minimum low frequency current at which this phenomenon still exists, corresponds approximately to 50 Hz , i.e. the most wide-spread industrial frequency.

2. It is possible that at presence of the external very low frequency current, which density level lays in the limits: $J_{\text{lim}0}^{\text{ext}} < J^{\text{ext}} < J_{\text{lim}1}^{\text{ext}}$ including smaller or equal to the permitted level, brain "adjusts" its work so that suppression of its own excitation signals does not occur, enlarging amplitude of these signals: $J^{\text{ax}} > J_{\text{min}}^{\text{ax}}$. It is possible also that this "tuning" acts some time after removal of the external EMF while brain will not adapt again to the EMF absence, as it was observed in experiment when EEG levels were greater some time after lifting of the low frequency EMF irradiation [2]. It may be also a cause of pain and sensitivity thresholds decrease some time after removal of the low frequency magnetic field exposure (see [12]) as at greater levels of action potentials brain may be more sensitive to lower levels of external pain effects.

Abstract

The exact mechanism by which electromagnetic fields affect bone and other tissues has yet to be cleared. Several mechanisms have been proposed, among them changes in cellular ionic calcium, modified receptor and messenger behavior, increased synthesis or degradation of substances, and even direct interaction with genes. Several in vivo studies were conducted to evaluate the effect of pulsed electromagnetic field (PMF) on the healing of skin wounds in rats. Variable results were reported. In some of these studies, exposure of wounds to PMF resulted in a higher rate of wound contraction (WC), enhanced cellular organization, and earlier collagen formation and maturation. However, several other reports failed to show any beneficial effect of PMF on the healing of skin wounds in rats. The aim of this study was to investigate the possible effects of a specially pulsed magnetic field (PMF) on skin wound healing in rats. Thirty male Sprague-Dawley male rats were used in this study. After anaesthetizing and shaving a paired full thickness incision wound (30 mm in length) was made on each side of the dorsal midline of the rats. The rats were randomly divided into three groups each containing 10 rats. Control and two treatment groups which were exposed to 0.45 ms pulse rates of 2.2 kHz. Treatment group1 were exposed PMF (5 mT) for 30 min a day for seven days and treatment group 2 were exposed PMF (2.5 mT) 1 hour a day for seven days after surgery. Control group were subjected to the same procedure, but with the PMF device not activated.

Key words: PMF, wound healing

Introduction

The process of regeneration and repair following injury represents one of the most fundamental defense mechanisms of an organism against environmental damage. Biological processes such as inflammation, proliferation, wound contraction and remodeling lead to the scar formation. Certain systemic diseases, such as injuries to the nervous system, metabolism and aging, have negative influence on the healing process, and lead to chronic wound formation. The use of pulsed magnetic field (PMF) for selective control of cellular function has given biology and medicine a new dimension. PMF stimulators with different characteristics were designed to induce voltages similar to those produced normally, during mechanical deformation of connective tissue. Researchers have used PMF stimulators to promote healing, but the results differ significantly from one another and there are discrepancies between the uses of PMF parameters. Further studies are needed to determine the optimal PMF parameters for the acceleration of wound healing. This study was designed to compare the different PMF pulse rates on skin wound healing in rats.

Milgram et al., (2004), objected to examine the effect of high intensity, short duration PMF on the healing of full thickness skin wounds in rats. Certain type of PMF did not have a significantly beneficial effect on wound healing. Wound healing is characterized by the restoration of the epithelial surface. The process of second intention wound healing consists of contraction and epithelialization.

Basset et al., (1974) including peripheral nerves for regeneration. The influence of PMF on nerve regeneration in vivo has been reported to be acceleration of the recovery of function following peripheral nerve crush or transection and exposure of the proximal nerve segment.

De Haas W.G., Lazarovici M.A., and Morrison D.M. (1979) the object of this experimental work was to evaluate the effect of a noninvasive method of electrical stimulation on the healing of freshly- created osteotomies of the rabbit radius. The apparatus consisted of a solid core electromagnet energized by a square wave unidirectional current. The magnetic field was pulsed transversely across the osteotomy site of the radius while the animal was confined to a restraining device 6 hours daily for 5 days per week. In one group of animals the influence of different pulse frequencies, using 0.1 Hz, 1 Hz, and 4 Hz, was evaluated, while the period of stimulation was kept constant at 2 weeks. In another group of animals, exposure was continued for 3 and 4 weeks while the pulse frequency was kept constant at 1 Hz. Histologic and radiologic comparison with control animals revealed that the initiation of the healing process can be accelerated in magnetic fields pulsed at 1 Hz, but that this effect is not maintained, and that the total period of time required for union is not significantly shortened. In view of these findings, this form of treatment is not recommended for clinical use in the treatment of recent fractures of long bones.

Ieran et al., (1990) PMF have been used clinically for the treatment of chronic skin ulcers of venous origin in humans. In a double blind study PMF have been used clinically for the treatment of chronic skin ulcers of venous origin in humans. In a double blind study the PMF treated group showed no worsening of any the ulcers, whereas four ulcers worsened in the control group.

Stiller et al., (1992), Ieran et al., (1990) by the end of the study, the treated group showed an increased number of healed wounds and a decrease in the rate of recurrence of venous ulcers, compared to the control group. In a multi centre study, a portable PMF device for home use was tested. Fifty percent of the ulcers in the treatment group healed or markedly improved, while none of the ulcers in the placebo group had healed. In the treatment group, no worsening was seen in any of the ulcers, while 54% of the ulcers in the control group exhibited worsening of the ulcers.

PMF Signal Generation and Exposure

The system was fed by a function generator (custom made in the department), producing a 2.2 kHz sine wave with 0.45 ms repetition time. The output of the function generator was connected to the Helmholtz coils: two identical coils (each of 300 turns of enameled copper wire with 0.4 mm radius) were mounted coaxially at a distance of one coil radius (13 cm) from each other to produce a highly uniform horizontal field between them. The coils were connected to the PMF generator.

The pulse duty was defined as the percentage of the time during which the voltage is switched on in one cycle. Helmholtz coil, producing 2.5 mT and 5 mT field effective intensity on the surface of rat skin. During the experiments, field intensity was measured by Philip Harris Probe (Shenstone/England) and Chauvin Arnoux Max3000 TRMS Multimeter (Paris/France). Unilab, Digital Gauss/Tesla Meter (Blackburn/England) was used for purity of the field. Maximum variation was less than 1%. Validation of the intensity measurement, axial magnetic field between the coils was also calculated.

Material and Methods

Thirty Sprague-Dawley male rats, 8-10 weeks old, weighing 200-250 g were used. They were kept in standard cages, food and water were available to them without any restriction. The temperature in the room was $20 \pm 2^{\circ}\text{C}$, the light cycle was 12/ 12-h light/dark schedule. Anesthesia was performed by the intra-peritoneal injection of ketamine HCL, 100 mg/kg and pompun, 10 mg/kg, 10 minutes before surgery. After shaving and cleaning, a pair of full thickness incisions (30 mm in length) was made parallel to and at a distance of 1.5 cm on each side of the dorsal midline. Then the animals were divided into three groups. Treatment group1 were exposed PMF (5 mT) for 30 min a day for seven days and treatment group2 were exposed PMF (2.5 mT) 1 hour a day for seven days after surgery. Control group were subjected to the same procedure, but with the PMF device not activated..

Discussion

Published reports indicated that the PMF stimulators may promote wound healing, but this depends on parameters such as frequency, intensity, exposure time and orientation of PMF. It was suggested that the suitable dosage and optimum PMF parameters involved in wound healing be found. The purpose of this study was to investigate the effects of pulse rates of PMF on skin wound healing in rats.

The animals in the sham group were kept in the restrainer inside the unenergized coil. These conditions may increase stress or temperature of animals, they did not affect wound healing time significantly and it was seen that the animals adapted to these conditions very soon.

Goldman et al.,(1998) have shown enhancement of fibroblast proliferation in response to certain conditions of the electric field (41 mv/m, 10 Hz) and Katsir et al. showed that chick embryo fibroblast proliferation was modified by EMF (60 Hz, 0.7 mT).

Berg et al., (1997) showed that the proliferatory response of yeast to electromagnetic field is frequency dependent and there is a window so that a high proliferation is detected at 15 Hz and a minimum proliferation at 40 Hz. These reports confirm our results in that there is a window between 10 to 80 Hz pulse rates (which is around 20 Hz). The significance in the absolute values and the normalized wound maximal lengths for the 20 Hz group compared to the sham group, verifies that the PMF with 20 Hz pulse rate accelerates wound healing. Our results on the wound surface area indicate that PMF stimulation does not affect wound contraction in rats which is in keeping with Scardino et al. that showed PMF had a positive effect on epithelization only.

Based on the results obtained in this study it could be concluded that PMF stimulators (which could later become a practical tool for clinical use) are effective devices for the acceleration of wound healing but further studies are required to determine the optimal frequency, direction and intensity of the PMF to be used in soft tissue healing and two clarify the exact mechanisms in involved in this phenomenon.

Fig 4. PMF power density

Power spectrum investigation has been conducted by using MATLAB software. Obtained spectrum density of pulsed magnetic field has been shown in Figure 4. As shown in Figure 4 fundamental component of RF energy must be in frequency about 250 Hz. So the main effective portion might be affected calcium permeability of cell membrane .It is known that permeability of cell membrane provides calcium efflux. Consequently target tissues related to wound healing affected by our used waveform.

Fig.5 and Fig. 6 shows the effect of various pulse rates on wound healing.

Fig 5. 3rd day's healing results

Fig 6. 7rd day's healing results

Conclusions

Changing rate of collagen fibrous and inflammation infiltration are shown in Fig 5. and Fig 6. At the end of the one-week process, decreasing in inflammation infiltration and increasing in collagen fibrous was observed. At incision on dorsal midline, 5 mT a day exposure can decrease healing rate half amount compare to control group. Exposure of 2.5 mT a day can increase the healing rate double amount to control group. The result of beneficial effect about wound healing was found in case of giving exposure with proper PMF. In the study similar results were found as in the scientific literature. Wave shape is as known the waveform which is used by Basset. Using proper exposure type can augment healing rate. The lower the exposure duration, the faster the healing occurs. It is agreeable that in the future, accelerated studies focused on waveform, frequency, power density, and different cell type will give reasonable interesting results.

Abstract

It was abundantly but also roughly reported that extremely low-frequency magnetic fields interact with biological systems and in particular with excitable cells, but it remains obscure the mechanism(s) by which ELF are transduced into biological signals. To test if the presence of 50Hz ELF modulates in vitro the activity of excitable cell models, we analysed some features concerning the intracellular calcium homeostasis. In fact, the spatially and temporally defined intracellular calcium variations are the transductive events of numerous extracellular stimuli and this ion can modulate cellular excitability.

Using a single cell approach and a confocal microscope supplemented with a specially designed Helmholtz coils, we recorded intracellular calcium variations during ELF exposure of PC12, GL15 and C2C12 cell lines resembling neuron-like, glial and muscle model respectively. The acute cellular response to ELF was different in each cell line. We observed a differently modulated spontaneous calcium oscillations related to the ELF presence in differentiated C2C12 cells or in undifferentiated GL15 ones; in the other cell models there were not any significant effect in the same experimental conditions. These effects, probably, differently influenced the chronic response on calcium channels, as was revealed by experiments on cell-free samples from 10 days exposed cells.

Introduction

The biological effects of extremely low frequency electromagnetic fields (ELF-EMF) have fascinated scientists for a long time. But it is only during the past decade that the study of EMF interactions with whole organisms or isolated cells has become an increasingly recognized area of research within the biological sciences thank to an increasing number of experimental findings confirming that, under certain conditions, the non-ionizing electromagnetic energy can influence physiological processes in organisms (Gartzke and Lange, 2002; Vaughan et al, 2005). Even if numerous hypotheses have been suggested, none are convincingly supported by experimental findings. Various cellular processes, and systems can be affected by ELF-EMF exposure: i.e. cell membranes, general and/or specific gene expression, cell proliferation and differentiation, metabolic pathways and many other physiological mechanisms correlated directly or indirectly with cell viability (Repacholi and Greenebaum, 1999; Sieron et al, 2004; Ivancsits et al, 2005).

More recently, Simko and Mattsson (2004) suggested that ELF-EMF exposure is capable of increasing intracellular production of free radicals. These are intermediates in natural processes and could be the initial stimulus inducing a first response which then enhances (depending on cell type and status) the release of free radicals (Wolf et al, 2005) in turn leading to different biological events (Droge W, 2002). Mitochondria are the main sites of reactive oxygen species (ROS) formed as a side-product of oxidative phosphorylation, since electrons flowing from reduced substrates are occasionally transferred to oxygen to form superoxide anion and derived products (Chen et al, 2003).

If ROS generation and accumulation can be considered the first cellular event of an ELF-EMF exposure, the modification of Ca^{2+} homeostasis is surely one of the most important mechanisms by which ROS explicate their multiple actions into the cell (Camello-Almaraz et al, 2006). In the past years, many data obtained in various laboratories, showed that the ELF-EMF exposure was able to induce modifications of cytoplasmic Ca^{2+} levels which can be related to different physiological mechanisms: i.e. differentiation of chromaffin cells into neuronal-like cells (Morgado-Valle et al, 1998); cell death by apoptosis induced by several agents in different human cell systems (Fanelli et al, 1999); functional modifications of cells of the immune system (Walleczek J, 1992); etc. All these effects, and more others, can be attributed to modifications of Ca^{2+} homeostasis by ELF-EMF exposure throughout different mechanisms such as the involvement of P2Y membrane receptors (Takahashi et al, 2005); the activation of mechanically operated stretch-activated Ca^{2+} channels (Sun and Cho, 2004); the enhancing of the expression of voltage-gated Ca^{2+} channels (Grassi et al, 2004). All these pathways are constituted at least in part of ionic transmembrane channels that, above all in excitable cells, represent the main way for cell communication. The goal of this paper is to analyse some features involved in the homeostasis of intracellular calcium in excitable cells exposed to ELF-EMF at different intensities (0.1-1.0 mT). In particular we checked if

1. intracellular Ca^{2+} levels are changed
2. alterations of active or passive Ca^{2+} transport through cell membranes can be postulated
3. levels of some proteic factors, directly linked to Ca^{2+} activation, were modified

Results. The experimental plane regards the study of the possible influences of ELF-EMF on calcium homeostasis of excitable cells. For this reason, we used PC12, GL15 and C2C12 cell lines resembling neuron-like, glial and muscle model respectively. The presence of ELF-EMF influences the oxidative system of some excitable cells (Marigiò et al., 2006) and also in this study some tested cell lines showed ROS production and/or mitochondrial membrane potential variations. Using a confocal microscope equipped with Helmholtz coils, we monitored the cells producing ROS (DCF labelled cells) or their mitochondrial membrane potential (JC-1-labelled cells) during a short exposure time (30 min) to 1.0 mT ELF-EMF. In these conditions, PC12 and GL15 populations showed an increased percentage of cells revealing increased ROS production (3 fold or 10

fold increase compared to PC12 or GL15 controls respectively), while in C2C12 cells no differences compared to control cells were detectable. In addition mitochondrial membrane potential variations were undetectable in PC12 cells, while GL15 and C2C12 cells showed a decreased potential compared to control cells.

The tested cell lines have a peculiar feature common to other excitable cells, which is to show spontaneous intracellular calcium ($[Ca^{2+}]_i$) variations. Using the above described experimental single cell approach and a calcium specific fluorescent dye (FLUO4/AM), we assayed spontaneous $[Ca^{2+}]_i$ variations during 30 min exposure to 0.1 or 1.0 mT ELF-EMF. Figure 1 shows selected representative frames (0, 15 and 30 min) depicting Fluo4-loaded cells (A) and temporal analysis of single cells (B). Data derived from these experiments showed that the spontaneous $[Ca^{2+}]_i$ variations were increased in differentiated cells, above all in NGF-differentiated PC12 cells and in C2C12 myotubes in all experimental conditions (Fig. 1, C). In addition, while no PC12 phenotype was sensible to the presence of ELF-EMF (0.1-1.0 mT), both undifferentiated and differentiated GL15 cells and C2C12 myotubes showed increased spontaneous $[Ca^{2+}]_i$ variations during short ELF-EMF exposure time (30 min) (Fig. 1, C).

Figure 1: Temporal $[Ca^{2+}]_i$ analysis. A: Confocal representative images, acquired at 0, 15 and 30 min, show a pseudo-color representation of Fluo4-loaded cells during a temporal analysis; the pseudo-color bar located to the left of the confocal images indicates a color scale from blue to red related to low (blue) and high (red) Ca^{2+} levels. B: Traces represent the possible $[Ca^{2+}]_i$ variations in cells observed in presence or absence of ELF-EMF: a represents no calcium variations, b high frequency calcium variations, c a slow calcium increase and d a single increased pulse of calcium; the traces are the ratio of the single Fluo4-loaded cell fluorescence at time range from 2 to 30 min (f) to the mean value of fluorescence intensities after 2 min when, in exposed cells, ELF-EMF were produced (f_0), as a function of time. C: Graphs represent the cell percentage of spontaneous variations (shown in B) in undifferentiated (undiff) or differentiated (diff) PC12, GL15 and C2C12 cells; bars are mean \pm SEM, $n=5$, * $p<0.05$ and ** $p<0.01$.

Longer cell exposure (3 and 10 days) to ELF-EMF modified basal $[Ca^{2+}]_i$ (Fig. 2, A and B). In particular after 3 days exposure at 0.1-1.0 mT ELF-EMF, GL15 cells showed significantly higher basal $[Ca^{2+}]_i$ compared to controls; PC12 cells revealed the same increased when exposed to 1.0 mT ELF-EMF after 3 or 10 days exposure, no significant difference was observed after 0.1 mT ELF-EMF exposure. C2C12 cells didn't show any differences at 3 days ELF-EMF exposures, while these cells showed increased basal $[Ca^{2+}]_i$ in respect to controls after 10 days exposure to 0.1 or 1.0 mT (Fig. 2, A and B).

Figure 2: Basal $[Ca^{2+}]_i$ recorded in cell suspensions after 3 (A) or 10 (B) days (3day- or 10day-cultured) exposure to 0 (Control), 0.1 or 1.0 mT ELF-EMF. Bars are mean \pm SEM, n=5, *p<0.05, **p<0.01 and ***p<0.001.

The changes in basal $[Ca^{2+}]_i$ after ELF-EMF exposure could be determined by modifications in the calcium homeostatic system. For this reason we checked some elements involved in calcium homeostasis on long time exposed cells (3 or 10 days to 0.1 or 1.0 mT ELF-EMF). They were: two calcium regulated proteins (calmodulin and calcineurin); the functionality of calcium channels characteristic of excitable cells, voltage-gated dihydropyridine-sensitive calcium channel (DHPR) and store ryanodine-sensitive channel (RYR); Ca^{2+}/Mg^{2+} ATPase pump activity.

Figure 3: Representative Western blots of calcineurin (Cn) and calmodulin (CaM) in PC12 cells grown in absence (C) or in presence (0.1 or 1.0 mT) of ELF-EMF for 3 or 10 days. The graphs show the summarized densitometric analysis of Western blots of calcineurin and calmodulin in the tested cells. Bars are ratios between ODxmm² of each band related to control (C) proteins and ODxmm² of the band related to 0.1 or 1.0 mT exposed cells proteins.

Calcineurin levels revealed by Western blot analysis appeared increased in extracts from GL15 cells exposed for 3 days at 1.0 mT ELF-EMF or in those from PC12 cells exposed for 10 days to 1.0 mT ELF-EMF; in the other tested cells no modification was observed in any experimental conditions (Fig. 3). The calmodulin levels appeared increased only in PC12 cells exposed to 1.0 mT for 3 or 10 days (Fig. 3).

Figure 4 shows the data collected from experiments on cell extracts assayed for the functionality of DHPR and RYR channels and ATPase activity.

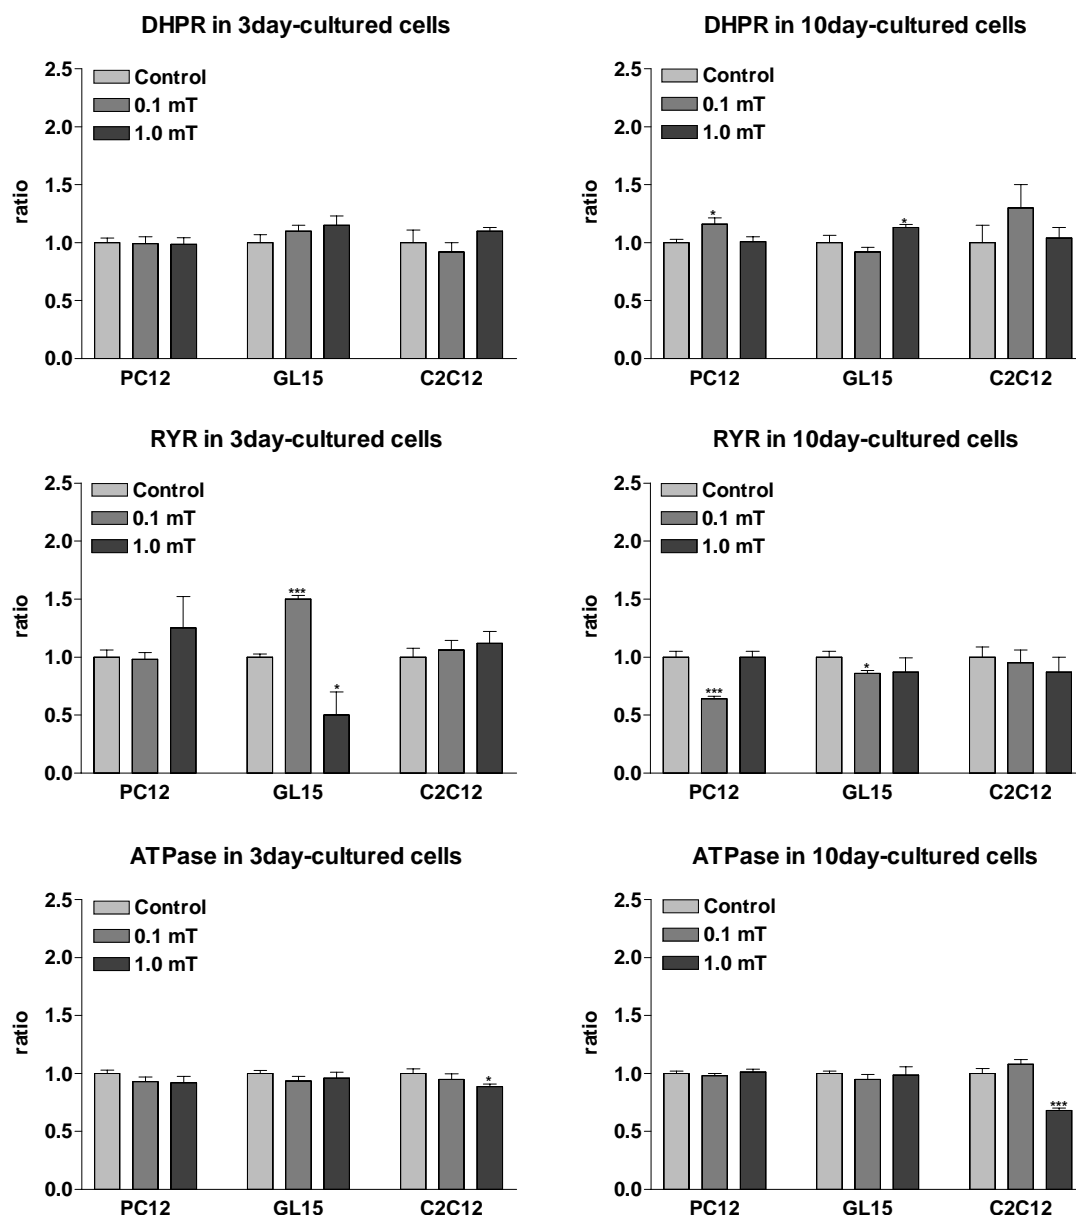

Figure 4: Functional assays on PC12, GL15 and C2C12 cells extracts. After 3 or 10 days (3day- or 10day-cultured cells respectively) exposure to 0 (Control), 0.1 mT or 1.0 mT ELF-EMF, cells were collected, homogenized and assayed for DHPR or RYR binding (calculated as pmol/mg protein and reported as ratio between treated and control cells) and ATPase activity (calculated as specific activity and reported as ratio between treated and control cells). Bars are mean \pm SEM, n=5, *p<0.05, **p<0.01 and ***p<0.001.

The DHPR and RYR binding assays permitted to monitor the presence of these channels on tested cells, in addition RYR binding experimental protocol revealed the functionally opened RYR channels. The number of DHPR appeared significantly increased on 10 days exposed PC12 and GL15 cells treated with 0.1 and 1.0 mT respectively. Fewer opened RYR channels appeared on 10 days and 0.1 mT exposed PC12 and GL15 cells, in the latter cells this result was evident also at 3 days and 1 mT exposure, while the opened RYR channels increased on 3 days and 0.1 mT exposed GL15 cells. The ATPase assay revealed a decreased ATPase activity on 3 or 10 days and 1 mT exposed C2C12 cells.

In conclusion each cell line showed a peculiar pattern of functional activities probably depending on their biological features.

Discussion. In the excitable cells, the Ca^{2+} ion has shown to play an important role in a wide variety of cellular

functions, such as that related to cell differentiation which involves nerve or muscle growth factors. For this reason, all changes to its cytoplasmic levels and/or transport can be the beginning of modifications able to modify, sometimes also radically, the functional capacity of the cell.

Cells exhibit several Ca^{2+} -mobilizing messengers, which transduce a large variety of extracellular stimuli regulating various intracellular Ca^{2+} -sensitive targets. Recent studies suggest that agonists differentially select their characteristic Ca^{2+} signals but it is still unclear whether different messengers mediate different functions or whether they act in a redundant fashion (Berridge et al, 2000). It is also possible that Ca^{2+} variations, induced by a specific source, are able to activate a sort of negative feed-back mechanism by which the cause of these variations can be suppressed. If this does not happen, then a measurable effect on some specific functional aspects of cell life must take place.

Under our conditions the first cause of Ca^{2+} overload can be found in the ROS generation triggered by ELF-EMF exposure. In fact, in at least two of three tested cell lines (PC12 and GL15), a significant increase of ROS, probably generated from the uncoupling of mitochondrial activity, was evident. As reported by several authors, a close relation between cytoplasmic Ca^{2+} variations and increase of ROS production exists under different experimental conditions. For example: (i) in cardiac tissue, a cytosolic, and subsequently mitochondrial, Ca^{2+} overload impaired mitochondrial bioenergetics (Solaini and Harris, 2005); (ii) in neurons, transient deprivation of oxygen and glucose during temporary ischemia coupled with elevation in cytosolic Ca^{2+} concentration triggers ROS generation and mitochondrial permeabilization, resulting in neural cell death (Brailoiu et al, 2006). Also under our experimental conditions, a significant modification of $[\text{Ca}^{2+}]_i$ probably dependent on ELF-EMF intensity and/or exposure time, can be observed. Thereafter also some aspects of basal Ca-dependent activity as well as the spontaneous spikes generations, seemed to be influenced from the presence of electromagnetic fields. In fact, we observed differently modulated spontaneous calcium oscillations related to the ELF-EMF presence in differentiated C2C12 cells or in undifferentiated GL15 ones. In this case, it is important to note that modulations of calcium activity was observed during ELF-EMF exposure of single living cells, and the unique experimental procedure used, permitted to strictly correlate, for the first time, the Ca^{2+} variations and the presence of the electromagnetic field. On the other hand, the results from experiments carried out to detect some modifications of Ca^{2+} transport system remain without a clear and complete explanation. This fact could be due to physiological adaptive mechanisms present in the cells. Moreover, it is worth noting that these experiments were performed on cell-free substrate after several days exposure to ELF-EMF, so that the slight, but significant effects observed could be considered other proof of the existence of an interference mechanism induced by ELF-EMF on Ca^{2+} homeostasis

Summary

Cells possess several Ca^{2+} -mobilizing messengers, which couple stimulation at the cell surface, by a multitude of extracellular factors, to the regulation of intracellular Ca^{2+} -sensitive targets. As reported by several authors, a tight relation between cytoplasmic Ca^{2+} variations and an increase of ROS production under different experimental conditions, exists. In particular, the presence of ELF-EMF, with an intensity ranging from 0.1 to 1.0 mT, was able to induce qualitative and quantitative modifications of Ca^{2+} homeostasis (with different features in different cell lines) probably dependent on ELF-EMF intensity and/or time exposure.

Acknowledgments

We wish to thank Dr Cristina Puglielli for her technical assistance in basal $[\text{Ca}^{2+}]_i$ measurements. This study was supported by grants from MATT (5376/2002/SIAR; DSA/2004/0026772)

Appendix

Instrumentation. The 50Hz electromagnetic fields were generated by two different devices: a solenoid and a pair of Helmholtz coils. These devices were planned and built to deliver variable, homogeneous, sine-wave alternate current magnetic fields with 50 Hz frequency and intensities ranging between 0.1-1.0 mT \pm 2%. The horizontal cylindrical solenoid (length=340mm, diameter=113mm), on a supporting base, was supplied by a power supply Elgar Electronics (mod. CW-801P). The solenoid was used in an incubator (5% CO_2 and 37°C) for long time continuous cell exposures (1-10 days) during which the solenoid's eventual added temperature was negligible (photo A). The pair of Helmholtz coils (r=445mm, distance between coils=400mm), producing homogeneous magnetic field over the specified volume-under-test corresponding to the cell chamber, were located in the working zone of a confocal microscope and connected to a power supply Elgar Electronics (mod. CW-1251P) (photo B). The coils were used to generate 0.1-1.0mT ELF-EMF for short time cell exposure (30 min) during in vivo cell analysis (ROS production, mitochondrial membrane potential variation, $[\text{Ca}^{2+}]_i$ variation).

A: Solenoid in a CO₂ incubator

B: Confocal microscope equipped with Helmholtz coils

Cell culture. C2C12 and PC12 (American Culture Collection) and GL15 (functionally characterized in our lab, Mariggiò et al BMC Physiology 1:4, 2001) were cultured as exponentially growing cells in growth medium (GM). The GM for C2C12 and GL15 contains Dulbecco's modified Eagle's medium (DMEM), 10-20% foetal calf serum (FCS), 2-4 mM L-glutamine and 100 UI mL⁻¹-100 µg mL⁻¹ Penicillin-Streptomycin. The differentiative phenotype was induced in C2C12 and GL15 cells in GM supplemented only by 2% FCS for 7-10 days. The GM for PC12 cells contains RPMI 1640 with 5% FCS and 10% horse serum, glutamine and antibiotics as mentioned previously. Reagents for cellular cultures were purchased from Gibco (Paisley, Scotland, UK). In PC12 cells, the differentiative phenotype was induced in GM containing 50ng/ml nerve growth factor for 7 days. The cells were seeded on Petri dishes in GM and routinely sub-cultured every three days C2C12 and GL15 and weekly PC12 (Mariggiò et al, BMC Physiology 1:4, 2001; Guarnieri et al, Neuroscience 128:697-712, 2004; Pietrangelo et al., J Physiol.572.3:721-733, 2006). The PC12 cells were cultured on Falcon flask and plated for experiments on collagen-treated wells.

[Ca²⁺]_i and ROS measurements. We plated the cells on glass coverslips that were incubated for 30 min at 37°C in normal external solution (NES) supplemented with 10 mg mL⁻¹ BSA and 5 µM FLUO4 AM or H₂DCF-DA (Molecular Probes, Eugene, OR, USA) for [Ca²⁺]_i or ROS determination respectively. The NES solution consisted of 10 mM glucose, 140 mM NaCl, 2.8 mM KCl, 2 mM CaCl₂, 2 mM MgCl₂, and 10 mM HEPES, pH 7.4. After Fluo4-AM incubation, cells were rinsed with NES and observed. The images were collected using a Bio-Rad MRC-1024 ES confocal system (Bio-Rad Microscience Ltd, Hemel Hempstead, UK) connected to an inverted microscope Zeiss Axiovert 100 equipped with 63x/1.25 PLAN NEOFLUAR oil immersion objective and Helmholtz coils described above. For Fluo4 fluorescence, as well as that of DCF, excitation was fixed at 488 nm and emission was set at 522 nm using a bandpass filter (bandwidth±32 nm). The laser potency, photomultiply and pinhole size were kept constant for the whole experiments. Images were acquired, stored and off line analyzed. Traces deriving from total cell area were calculated as f/f_0 where f is the fluorescence emission of a single FLUO4 (or H₂DCF-DA) loaded cells at times ranging from two to x seconds and f_0 is the mean value of fluorescence intensities of the same cell calculated among all the images before turning on the coils. Graphs were plotted using Prism 2.0 (GraphPad Software, San Diego, CA, USA).

Spectrofluorimetric determination of basal [Ca²⁺]_i. For basal [Ca²⁺]_i determination on cell suspensions, after 3 or 10 days ELF-EMF exposure, the cells (PC12, C2C12 and GL15) were detached and washed by gentle centrifugation. The cells, resuspended in NES, were loaded with 5 µM Fura 2-AM for 30 min at 37°C and treated for 5 min with 250 µM sulphhydrylase then collected in the quartz cuvette and analysed using LS-5B Perkin-Elmer spectrofluorimeter. The [Ca²⁺]_i was calculated using the formula: $[Ca^{2+}]_i = K_d (F - F_{min}) / (F_{max} - F)$, where F_{max} and F_{min} were the fluorescences recorded at the end of each experiment, after the addition of 1 µM Ionomycin and 5 mM EGTA respectively; K_d (224 nM) is the dissociation constant of Fura2 for calcium (Gryniewicz et al, J Biol Chem. 260:3440-3450, 1985).

Mitochondrial membrane potential measurements. These were determined using a carbocyanine dye JC-1 (Molecular Probes, Eugene, Oregon, USA) which is taken up by the mitochondria. When the transmembrane potential is high, like in normal cells, JC-1 forms red fluorescence dimers (J-aggregate), while when it is low the red fluorescence disappears and green fluorescence emission appears (monomer). Briefly, the cells on coverslips were incubated in growth medium containing 5 mM of JC-1 for 10 min. After being rinsed three times with PBS, each coverslip was observed and images were recorded with or without the ELF-EMF generated by Helmholtz coils applied to a confocal microscope (excitation was fixed at 488 nm and emission was set to either 522 nm, for green monomer, or 605 nm, for red J-aggregate, using a bandpass filter). To estimate the modification of fluorescence in mitochondria, the change in green and red areas was calculated for the whole image using Scion Image ver. beta 3b (Scion Corporation, Frederick, Maryland, USA). The red/green area ratio, resulting from each single image of the experiment was plotted against time (Castellano et al., Arch. Pharm. Pharm. Med. Chem. 333:373-380; 2000).

Western blots. PC12, C2C12 and GL15 cells were exposed to 0.1 or 1.0 mT ELF-EMF for 3 or 10 days. At the

end of the exposure the cells were collected, rapidly washed on ice with pre-cooled PBS and lysed in buffer containing (mM): 50 Tris-HCl, 100 NaCl, 50 NaF, 40 β -glycerolphosphate, 5 EDTA, 1% Triton X-100, 200 μ M NaOrthovanadate, 100 μ g/ml phenylmethylsulfonyl fluoride, 10 μ g/ml leupeptin, 5 μ g/ml pepstatin A, 10 μ g/ml benzamidine, pH 7.4. After vortexing for 5 min, the sample were centrifuged at 12,000 rpm for 10 min at 4°C. The protein content of the supernatant was quantified by a colorimetric assay (Bio-Rad Laboratories Srl, Milano, Italy). Samples containing 40 μ g of proteins were suspended in Laemmli buffer (8% SDS, 10% glycerol, 5% β -mercaptoethanol, 25 mM Tris-HCl and 0.003% Bromophenol Blue, pH 6.5), boiled for 5-10 min and electrophoresed on 10% SDS polyacrylamide homogenous slab gel (SDS-PAGE). Proteins were electroblotted onto a hydrophobic polyvinylidene difluoride membrane (Hybond-P Amersham-Pharmacia Biotech). The calmodulin and calcineurin proteins levels were detected with specific antibodies (monoclonal mouse anti-Calmodulin and polyclonal rabbit anti-Calcineurin, CALBIOCHEM, Germany). The antibodies were detected by chemiluminescence (ECL Amersham-Pharmacia Biotech).

Binding experiments and ATPase activity measurements. For [3 H]PN200-110 and RyR binding, and Ca^{2+} -ATPase activity the cells cultured in growth medium were exposed for 3 or 10 days to ELF-EMF electromagnetic fields at 0.1 and 1.0 mT intensity. At the end of the exposure times, the cells were sonicated (1 pulse 2 s^{-1} , 20-40 pulses) in a buffer solution containing 10 mM Hepes and 150 mM KCl. The dihydropyridine receptor (DHPR) concentration was determined according to the procedure of Renganathan et al. (J Membr Biol 157(3):247-253, 1997) using the radioligand [3 H]PN200-110. Sonicated cell proteins (40 μ g) were incubated in a final volume of 250 μ l binding buffer in the presence of 1 nM [3 H]PN200-110 per 1 h at room temperature, then the samples were filtered with Whatman GF/C filters and washed with 6 volumes of ice-cold washing buffer. Radioactivity was determined by liquid scintillation counting. Non-specific [3 H]PN200-110 binding was assessed in the presence of 10 μ M unlabeled nifedipine.

The sonicated cell proteins (25 μ g), in a final volume of 250 μ l, were incubated in a binding buffer (200 mM KCl, 10 mM HEPES pH 7.4, 100 μ M CaCl_2 , 1 μ g/ml pepstatin, 1 μ g/ml leupeptin) in agitation with 5 nM [3 H]ryanodine for 120 min at 37°C, then filtered with Whatman GF/C filters and washed with 6 volumes of ice-cold 200 mM KCl, 10 mM HEPES, pH 7.4 as described by Fanò et al. (J Muscle Res Cell Motil 22:345-351, 2001). The amount of bound [3 H]ryanodine was determined by liquid scintillation counting (Treves et al., Biochemistry 36:11496-11503, 1997).

Ca^{2+} -ATPase enzymatic activity was measured on total sonicated cell proteins according to the procedure of Fanò et al. (J Muscle Res Cell Motil 22:345-351, 2001). The assay was carried out in 1 ml incubation medium (in mM: 5 ATP, 1 CaCl_2 , 50 Tris-HCl buffer, pH 7.4) containing 25 μ g of proteins/sample. After 15 min at 37°C, the reaction was stopped by the addition of 1 ml of 5% TCA and the precipitate removed by centrifugation at 5000g for 10 min. The released orthophosphate was estimated on 1 ml of clear supernatant, according to Saini and Van Etten (Arch. Biochem. Biophys 191:613-624, 1978). Enzyme specific activity was expressed as μ mol of Pi released per min per mg of proteins (A.S.).

Statistical analysis of data was performed using Student's paired t-test, and automatically derived with Prism 2.0 software (GraphPad Software, Inc., San Diego, CA, USA).

THE EFFECTS OF DIFFERENT MAGNETIC FIELD INTENSITY TREATMENTS ON RAT ELECTROPHYSIOLOGICAL PARAMETERS

SEVGI GUNES, BELGIN BUYUKAKILLI

***MERSIN UNIVERSITY, MEDICAL FACULTY, DEPARTMENT OF BIOPHYSICS,
TURKEY***

gunessevgi@yahoo.com, bbuyukakilli@mersin.edu.tr

Abstract

In this study, we investigated the effects of different densities at daily life exposure of sinusoidal magnetic fields on the mass of rats and peripheral nerve regeneration. Magnetic field was applied to 40 rats for 4 hours per day for a week. One of the rat groups were separated as a control the others were separated for 10, 20, and 30 Gauss (G) magnetic field treatment. All of the rats were exposed to crush injury just before the treatment.

In the study, after crush injury of sciatic nerve in the period of first 3 days treatments of magnetic field showed no mass differences compared to control. But 7 days treatment of 30 G magnetic field decreased mass of the rats when compared to control while the other groups did not.

When the electrophysiological results were estimated, in terms of nerve regeneration, it could be suggested that both after 3 days exposition to injury and 7 days treatments of different magnetic field densities have no statistically important effect on the CMAP (Compound Muscle Action Potential) amplitude, area and the rate of conduction.

As a result, it is observed that the density and frequency of magnetic fields used in this study had no effect on transmission and stimulation of nerves consequently so was not effecting the nerve regeneration.

Key words: Electromagnetic field, nerve regeneration, rat mass.

Introduction

All members of modern societies constantly live in electromagnetic fields and waves which intensities are much higher than those found in the nature. The potential negative effects of those on human health continue to be the subject of controversy (1). Most public exposure to ELF fields comes from electrical appliances, household wiring, and AC transmission and distribution lines (2).

In this study we tested whether magnetic fields created with 50 Hz alternating current (AC) affects regeneration of the sciatic nerve or not.

Exposure to PEMF as a pretreatment prior to crush injury also resulted in acceleration of axonal regrowth (3;4). Research in cats and rats suggests that pulsed electromagnetic fields may accelerate the rate of peripheral nerve regeneration (5,6). Stimulation with a 50-Hz alternating magnetic field stimulated regeneration of sensory nerve fibers in the rat sciatic nerve (7). A high-intensity static magnetic field of 1 Tesla has no effect on peripheral nerve regeneration as determined by myelinated axon counts and electrophysiologic studies in our rat sciatic nerve model. Specific orientation of the sciatic nerve with respect to the magnetic field also has no effect on the rate of nerve growth. Periods of restraint of 12 hours per day for 4 weeks inhibit weight gain by rats but have no effect on nerve regeneration in this experimental system (8).

Kolosova et al. [1996] reported that the stimulation observed in the study may not be a direct effect of MWR on regenerating nerve fibers. In their study data show a stimulating effect of low-intensity MWR on regeneration of the rat sciatic nerve. MWR treatment of the femoral skin in the area of suture accelerates the growth rate of the regenerating nerve fibers and their functional maturation (9).

The biological mechanism of action of magnetic fields is poorly understood. Reports of changes in cell membrane permeability suggest that the physiological effect is connected with electrolyte ion exchange (10).

Mean body weights of exposed groups of male and female mice were similar to those of the control groups throughout the study (11). In the another study the data indicated that over 21 days, the PEMF field inhibited young rats ability to recover from the mass loss normally associated with stress from the start of the experiment. In contrast all older rats recovered more slowly than the control young rats in the same study (12).

Materials and Methods

Animals

In present study 40 female Wistar Albino rats (150–200 g) were used. 30 of them were experiment group and the others were the control group. The rats were 12 weeks of age. They lived at 12h light-dark cycle with diet and water available *ad libitum*, without any additional medication. Before the experiment, they are adapted these conditions in a week. The experiment group was divided into three groups. They were given 10, 20 and 30 G respectively. The magnetic field generation coils were not energized, and the control rats were exposed only to the ambient magnetic field in laboratory (0.4-0.5 G).

Surgical Procedure

All rats were operated on under intramuscular (i.m.) 50 mg/kg Ketamine Hydrochloride anesthesia. The sciatic nerve was exposed to biceps femoris muscle splitting incision unilaterally. Crush lesions were performed using a jeweler's forceps to prevent cutting when applied 15 sec, and the site of the injury was labeled with a 10/0 prolene suture attached to the epineurium. Following recovery from anesthesia, the rats were randomly assigned as a control group or experimental groups.

Magnetic Field Stimulation

A field of 10, 20 and 30 G as calculated from voltages induced in pick up standardized coil probe, placed midfield, was generated in a pair of Helmholtz coils 45 cm in diameter, with 160 turns of 2.2 mm gauge copper wire each. The coils were mounted on a plastic framework, 22.5 cm apart, and connected in series to a generator delivering a sine wave output current of 4.8 A at 50 Hz. Five rats were simultaneously put in a square, nonconductive plastic cage (35x20x45 cm) within the coils and left unrestrained. The coils were placed perpendicular to the table so the magnetic field was horizontal.

The rats were put in square plastic cages (20x20x30 cm) within the coils and exposed to the magnetic field for four hours on every seven days from the day of operation. The action potentials were recorded before experiment and after 3rd, 7th days of exposure to the electromagnetic fields by using a BIOPAC MP 100 Acquisition System Version 3.5.7 (Santa Barbara, USA).

Statistical Analysis

All statistical tests were performed with SPSS software (Statistical Package for the Social Sciences, SPSS, Inc., Chicago, IL, USA). Data obtained from study were compared by one-way ANOVA in term of differences. Bonferroni test was used for determining that the differences between each groups.

Results

The extent of nerve regeneration was studied by CMAPs. The amplitude, duration, area, and latency period of CMAPs were measured, and the conduction velocity of the nerve was calculated.

Table 1

Conduction Velocity (Effect of 50 Hz sinusoidal magnetic field exposure on regeneration of rat sciatic nerve)

Groups	Treatments (h/day)	Magnetic field intensity (G)	Before experiment measurements (m/s)		3 rd day measurements (m/s)		7 th day measurements (m/s)	
			Average	S D	Average	S D	Average	S D
Control	4	0	103.50	28.55	111.36	0.80	94.44	26.84
Group I	4	10	35.18	18.67	71.15	49.57	87.39	37.03
Group II	4	20	59.74	46.53	101.11	26.75	90.56	41.60
Group III	4	30	101.90	31.36	114.51	23.60	108.33	12.50

S D: Standard Deviation

CMAP rate analysis have showed that 3 days of 10 G treatment elongated duration compared to other three groups and 20 G treatment increased duration more than 30 G treatment. This results show that CMAP period increases while the intensity of magnetic field decreases. When compared to control, 7 days treatment of 20 G decreases total CMAP period more than the other groups. As a result, it is observed that the density and frequency of magnetic fields used in this study had no effect on transmission and stimulation of nerves consequently so was not effecting the nerve regeneration (Table 1).

In the study, after crush injury of sciatic nerve in the period of first 3 days treatments of magnetic field showed no mass differences compared to control. But 7 days treatment of 30 G magnetic field decreased mass of the rats when compared to control while the other groups did not (Table 2).

Table 2

Effect of 50 Hz sinusoidal magnetic field exposure on rats weights

Groups	Measurements	Average weights (g)	Standard deviation
Control (n=10)	1.	152.40	17.57
	2.	159.10	17.02
	3.	161.70	15.83
10 G Group (n=10)	1.	143.70	18.84
	2.	141.30	18.86
	3.	142.70	15.04
20 G Group (n=10)	1.	148.20	19.91
	2.	155.20	20.51
	3.	166.50	19.21
30 G Group (n=10)	1.	169.91	15.27
	2.	172.36	17.77
	3.	175.30	21.32

Conclusions:

We could not prove a neuroprotective effect of electromagnetic field in rat crush injury model using electrophysiological method.

Summary

In this study effects of weak, sinusoidal low frequency magnetic field (MF) stimulation on regeneration of the rat sciatic nerve were investigated. Forty Wistar rats were used: they were underwent unilateral sciatic nerve transaction injury, 30 of them were experiment group and the remaining 10 were control group. The experiment group with sciatic nerve lesion was divided into 3 groups randomly. After the injury all of the experiment groups were exposed to sinusoidal 50 Hz magnetic field of 10, 20 and 30 G respectively. During the experiment the rats were put between a pair of Helmholtz coils for a week for 4 h/day. The other ten rats were used for control.

When the electrophysiological results were estimated on the 3rd and 7th days after the injury, in terms of nerve regeneration, it could be suggested that treatments of different magnetic field densities have no statistically important effect on the CMAP amplitude, area and the rate of conduction.

CMAP rate analysis have shown that 3 days of 10 G treatment elongated duration compared to other three groups and 20 G treatment increased duration more than 30 G treatment. These results show that CMAP period increases while the intensity of magnetic field decreases. 7 days of treatment of 20 G found to decrease total CMAP period more than the control group. As a result, it is observed that the density and frequency of magnetic fields used in this study has no effect on transmission and stimulation of nerves, and also to the peripheral nerve regeneration.

In the study, after crush injury of sciatic nerve in the period of first 3 days treatments of magnetic field showed no mass differences compared to control. But 7 days treatment of 30 G magnetic field decreased mass of the rats when compared to control while the other groups did not.

Abstract

We compared the effect of microwave irradiation on the red fluorescent protein (DsRed) placed in a cylindrical resonant cavity with that of conventional heating. Our measurements show that the fluorescence intensity in either case decreases by $\sim 1\%$ per degree centigrade, indicating that the microwave effect on the sample is mostly a thermal one.

1. Introduction

In this work we studied the influence of microwave field on the DsRed, a red fluorescent protein (RFP) from *Discosoma coral*¹. The DsRed has a very stable three dimensional beta-can barrel structure, but its emission spectrum is shifted to longer wavelength, with a maximum intensity at $\lambda=583\text{ nm}$ ^{2, 3}. The sample, placed in a cylindrical cavity, was excited by the CW excitation at 488 nm by an Argon laser. We performed our experiments on RFP in a buffer solution, and have monitored changes in its photoluminescence under microwave irradiation and compared it to the changes in fluorescence under conventional heating. Previous studies indicate that the microwave field effect on proteins in solution and on living tissues can not be entirely reduced to heating^{4, 5, 6, 7}, while when the biomolecule is in the crystalline form, the effect of microwave irradiation is indistinguishable from conventional heating⁸. Our group has recently found a specific effect of the microwave field on the Enhanced Green Fluorescent Protein fluorescence in solution⁹. It is surprising since the theoretical analysis of microwave interaction with biological system does not leave many possibilities for non-thermal microwave effect on biological system. Adair¹⁰ showed that the resonance excitation of biological molecules in solution at microwave frequency is highly improbable. Foster¹¹ demonstrated that thermal gradients on the nanometric scale are exceedingly small. The purpose of our present approach is to study the effect of microwave field on the protein fluorescence in solution in real time.

2. Experimental Setup

We placed a transparent glass pipette filled with buffer solution containing DsRed inside an X-band TE₀₁₁ cylindrical resonant cavity (Fig. 1.). We drilled two small holes in the sidewalls of the cavity to introduce laser beam and to observe fluorescence. The pipette is mounted slightly off-center. The cavity is fed using a HP 83623A synthesized sweeper. We directed a 488 nm Argon laser beam (Omnichrome Series 43) through the pipette and picked up the fluorescence at 90° using an objective lens coupled to a monochromator (DK480) through an optical fiber (Oriel, Model 77539). The monochromator is connected to a cooled photomultiplier (Product for Research, Model TE177RF) operating in the counting mode (SR400 Two channel Gated photon counter). In some experiments we also used a stereo microscope (Zeiss, Stemi 2000-c) connected to a digital camera.

Microwave and temperature effect on the Dsred protein fluorescence

Fig. 1. Experimental setup - Top view. The pipette with a fluorescing solution is mounted in the cylindrical microwave cavity operating at 9.5 GHz. The pipette is slightly off-center of the cavity and it is irradiated by the laser beam through a small hole in the cavity sidewall. The photoluminescence under microwave field is analyzed. The sample is visualized using a stereomicroscope and a digital camera.

3. Mode of operation

Our 63.5 mm diameter cylindrical cavity operates in the TE_{011} mode. Under this mode of operation the currents are annular and there is no electrical current flow in either the radial or longitudinal direction (Fig. 2.). This property enables us to fine tune the frequency by moving the piston-like end plate in and out. A brass screw is used to maximize the coupling between the cavity and the coaxial adaptor.

Fig. 2. (a) Cavity design – Cross sectional view. The microwave enters the cavity through a coax-to-waveguide adaptor and a coupling hole while the fluorescence exits from the other side of the cavity. (b) Cavity fields- Top view.

We measured microwave reflectivity using a vector network analyzer (HP 8510 C). Knowing the field distribution in the cavity, we placed the sample (10 mm long and 1.5 mm wide) slightly off-center where there is some electric field. Note, that the electric field in the center of cavity is zero. Care was taken not to destroy the Q-factor of the cavity (Fig. 3.).

Fig . 3. Microwave reflectivity, S_{11} , with (dashed line) and without (solid line) the sample in a TE_{011} cylindrical cavity. When the sample is placed inside the cavity the resonance curve is slightly perturbed.

Liquid crystal as a temperature indicator

A very important issue in our experiments is independent control of the sample temperature under microwave irradiation. The important requirement here is that the temperature sensor should not perturb microwave field. Therefore, rather than to use a thermocouple, we looked for other methods. We took a thin sheet of commercial film of cholesteric liquid crystal (LC) indicator which changes its color when its temperature is between 35°C- 36°C . Using a stereomicroscope and a digital camera, we first verified that the dry LC indicator alone doesn't change color even under a maximum microwave power of 250 mW. Since our buffer solution consists mainly of water, we filled the same amount of distilled water in a thin glass pipette (just as with the RFP sample), put it inside the cavity together with a small piece of LC (1.3 x 3.3 mm²) inside and watched for color changes as the incident microwave power is varied. Under maximal incident power the indicator changes its color. When the incident power gets smaller than ≈ 100 mW, the indicator changes. This means that at the incident power of ≈ 100 mW the temperature of the indicator is 35°C- 36°C, i.e. it exceeds ambient temperature (22°C) by 13°C- 14°C. Since the temperature rise is proportional to the incident microwave power, we conclude that each 1 mW of the incident microwave power results in the solution temperature rise of ~ 0.07 °C.

Fluorescence Spectrum measurement under conventional heating

To observe the temperature dependence of the RFP fluorescence upon conventional heating and in the absence of microwave irradiation, we used a CCD detector (MS 125TM 1/8m spectrograph, model 77400 Newport). The glass tube, which is sealed on one side and opened from another allows introduction of a small thermocouple inside the sample (RFP) near the laser-illuminated spot. The pipette with the solution was placed in a heated water bath. The fluorescence was picked up at 90° to the laser beam by a fiber bundle focusing assemblies (model 77799 Newport), coupled to the CCD detector and to the computer. As we slowly varied the water bath temperature, between 26° C and 36° C, we measured the fluorescence spectrum.

4. Experimental Results

The Fig.4 shows the DsRed fluorescence spectrum in the absence and in the presence of the microwave field. First we measured the spectrum without microwave irradiation (dashed line). Then we turned on the microwave for 30 sec., performed the measurement (solid line) and turned it off. Under microwave irradiation the fluorescence intensity is reduced. Having the relation between the microwave power and the temperature we see that there is ~1% fluorescence decrease per one degree centigrade. The process is reversible as can be seen by the spectrum marked by the squares.

Fig. 4. RFP fluorescence spectrum (normalized with respect to the fluorescence at 583 nm before irradiation) under 488 nm excitation at room temperature before, during and after microwave field. It is seen that under 100 mW microwave irradiation the spectrum is reduced mainly in the peak ($\lambda=583$ nm). Note a “valley” at 540 nm.

The next step was to measure the kinetics of microwave effect on the RFP fluorescence (**Fig. 5.**). We picked the wavelength of maximum intensity, turned on the microwave (100mW) and monitored the fluorescence decrease. Then we turned off the microwave and observed how the fluorescence reaches its pre-exposure level. As the power increases the fluorescence “valley” decreases.

Fig 5. Fluorescence (at $\lambda=583$ nm) variation upon switching the microwave field on/off. First arrow on the left upper side indicates the moment when the microwave irradiation is switched on while the arrow at the bottom indicates a moment when the microwave irradiation is switched off.

Fig. 6. A decrease in fluorescence (at 583 nm) as a function of the microwave power (dBm).

The effect of microwave on the DsRed should be compared to conventional heating of the protein. Figure 7 below shows the RFP fluorescence spectrum for two different temperatures measured with a CCD detector. Since the glass tube is placed inside a water thermal bath with a thermocouple inside the sample we can measure the fluorescence spectrum for different temperature. When the temperature is slowly increased

Microwave and temperature effect on the Dsred protein fluorescence

from 26°C to 36°C the fluorescence decreases by about 10%. Therefore there is a ~1% decrease per one degree centigrade.

Fig. 7. RFP fluorescence spectrum (normalized) under 488 nm excitation. The glass tube with the protein solution was placed in a heat water bath and the spectrum was measured for two different temperatures using a thermocouple inside the sample. Upon increasing the temperature the fluorescence decreases mainly in the peak (~583 nm).

Since the effect of conventional heating on the fluorescence spectrum of the RFP is wavelength-dependent we present below the temperature dependence of the fluorescence for several wavelengths.

Fig. 8. Normalized fluorescence as a function of the temperature for different wavelengths. Upon increasing temperature the fluorescence does decrease but in different proportion around the spectrum. Watch for example difference of the 580 nm and the 640 nm line.

Summary

Our present experiments indicate that the effect of microwave irradiation on the dsRed fluorescence in solution can be reduced to thermal heating. This is different from our recent experiments with another fluorescent protein⁹, EGFP, where we observed that the effect of microwave irradiation was stronger than the heating which accompanies microwave irradiation. Even though the GFP and the DsRed seem to share the same “barrel” form, the latest is known for his greater stability due to his oligomeric structure to elevated temperature and other physical factors². We are now studying the effect of microwave field on the EGFP in our cavity-based set-up as well as the microwave effect on the well-known fluorescence anisotropy of both proteins.

Acknowledgment

We are grateful to F. Sakran for all the technical help and to Dr. Tsafi Danieli and her group for there assistance with RFP handling. We are grateful to O. Popov and V. Lirtsman for the help in optical experiments and for the samples of RFP.

STUDYING THE EFFECTS OF THE STATIC MAGNETIC FIELD ON THE ENZYMES CATALASE (CAT) AND SUPEROXIDE DISMUTASE (SOD) ACTIVITY IN SUSPENSION CULTURE OF TOBACCO CELLS

PARVIZ ABDOLMALEKI, FAEZEH GHANATI

**FACULTY OF SCIENCE, TARBIAT MODARES UNIVERSITY, P.O. BOX
14115/175, TEHRAN, IRAN.**

The influence of the magnetic field on the enzyme activity depends on the intensity as well as the period of exposition. In this research the effect of a static magnetic field (SMF) with intensity of 10mT and 30mT on the enzyme activity of superoxide dismutase (SOD) and catalase (CAT) in suspension-cultured of the tobacco cells were investigated. Suspension cultures in the exponential phase of the growth were exposed continuously for 5 days each 5 hours to SMF of 10 and 30 mT. The result showed that the exposure to SMF caused an increase in the activity on the treatment cells (n=24) compared with the controls (n=24). The best obtained average for enzymes activity of SOD on treatment group was 0.88 ± 0.01 (Δ Abs/mg. protein) while the best obtained average for enzymes activity of SOD on control group was 0.55 ± 0.02 (Δ Abs/mg. protein). Similarly, the best obtained average for enzymes activity of CAT on treatment group was 296.61 ± 122.87 (Δ Abs/mg. protein) while the best obtained average for enzymes activity of CAT on control group was 162.72 ± 24.06 (Δ Abs/mg. protein). Our results showed that the exposure of treated cells with a SMF with 10 and 30 mt can cause an increase in the enzyme activity of SOD and CAT.

Introduction

Magnetic fields (MF) are widely distributed in environment and their effects are interesting with the burgeoning development of electrical machines [Ishisaka et al. 2000]. There are arguments for both positive and negative effects of EMF on living systems [Yoshikawa et al. 2000]. The exact mechanism of these effects remains unknown and still under investigation. The effects of electromagnetic field exposure on cells can be difficult to interpret because findings are often contradictory. Difficulties may arise because effects are small and because of variations in magnetic field parameters such as strength, duration of exposure and the type of magnetic field (AC or DC). Confounding variables can also arise from differences in the cell type and from the effects of differentiation cues [Mcfarlane et al. 2000]. One of the most important hypotheses is such fields cause an increase the average concentration of free radicals (oxygen free radicals), lengthen their life time, in living organisms which results in the formation of excessive amounts of active oxygen forms [Sobczak et al. 2002, Scaiano et al. 1994, Lee et al. 2004]. They induce change in enzyme activity, gene expression, and release of calcium from intracellular storage sites; affect membrane structure, cell growth, and cell death [Kwee and Rashkmark 1998, Olivares-Barnuelos 2004, [Robison et al. 2002]. Free radicals are very reactive and unstable molecular species that can initiate chain reactions to form new free radicals. Although formed as a result of a wide range of normal biochemical process, they are potentially damaging. Several mechanisms are in place to neutralize and endogenous enzymatic antioxidant defenses that generally hold the production of free radicals and prevent oxidant stress and subsequently tissue damage. The balance between the oxidants and the antioxidants may be disturbed by an increase in free radical production or by a reduction in antioxidants. This imbalance between the oxidants and the antioxidants can lead to oxidative stress which is a series of peculiar and potentially damaging biochemical reactions [Moustafa et al. 2001].

These mechanisms have been initially studied on plants after they used as target model in different stresses. The previous results showed that they produce large amounts of active oxygen species such as superoxide anion (O_2^-), hydroxyl radical ($^{\circ}\text{OH}$) and hydrogen peroxide (H_2O_2) that can result in photoinhibition and photooxidation. We considered the magnetic field as a physical stress and we intended to study the response of the selected cell plant in antioxidant defense systems. We assumed that this response is a protective mechanism that enables cells to survive. It is activated by a wide variety of environment stimuli, such as high temperature,

oxygen starvation, and heavy metals, as well as EMFs. We intended to clarify this point because we know that most organism have enzymatic systems associated with SOD and CAT to scavenge such active oxygen species. In the present research suspension-cultured tobacco cells (*Nicotiana tabacum*) were used as a model to evaluate the response of tobacco cells when it exposed to a static magnetic field. Also the intensity of the magnetic field on the rate of enzymes activity was investigated. Tobacco cells were considered as model because there is a potential to extract a homogenate and undifferentiated embryonic batches of cells through carrying out too many subcultures. Thus, the present study was designed to evaluate the effects of exposure to SMF on some parameters indicative of oxidative stress (SOD and CAT) in tobacco cells.

Suspension-cultured tobacco cells (*Nicotiana tabacum*) were initially grown in Linsmaier & skoog (LS) medium. The calli from which suspensions were established had been maintained in our laboratory for several years. We extract the suspension cultures after 52 subcultures. This provided a homogenate and undifferentiated embryonic batches of cells which could be considered as a good target for our study. Furthermore by doing so, it seems that no longer have they kept their original properties and their physiological response to static magnetic field resembles physiological response of a plant cells regardless of it species. The prepared cells were then incubated at 25°C in darkness on an orbital shaker at 100 rpm. The suspension of cells were then transferred (1.3gr fresh weight) at 7 day intervals [Kuboi and Kaji 1994] into 30ml of fresh medium in a 100ml Erlenmeyer flask. We initially extracted the growth and the differentiation indices of tobacco cell by studying the tobacco growth cells curve. The cells in the exponential phase of the growth curve were then exposed continuously for 5 days (from 3 to 7 sub-cultured) with exposure rate of 5 day to 10 and 30mT in a local designed SMF. The cells were harvested after 5day of treatment and frozen in liquid N₂ and kept at - 80 °C until used for biochemical measurements.

The apparatus (Fig.1) which we used to create the static magnetic field had two coils each with 3000 turns of 1mm of enameled copper wire. This provided a highly homogenous field enabling us to put our prepared cells into a large and homogenous field. To intensify the field we used iron surfaces that had been separated by diamagnetic materials to avoid the turbulence currents.

Thirty milliliter cell culture flasks containing tobacco cell cultures were put into the center of cylinder container (length 17cm) that allowed the placement of multiple or single flasks within apparatus simultaneously. The flasks were placed so that laid perpendicular to the direction of the generated magnetic field. The control samples were kept in the same condition regarding the temperature, humidity and light. Using the prepared calibration curve obtained for the apparatus to initialize a magnetic field with the intensity of 10mT and 30mT, a current of 5 ampere and 25 ampere were transferred through the circuit respectively.

Frozen samples (200 mg fresh weight) were homogenized in 3 ml HEPES-KOH buffers (pH 7.8) containing 0.1 mM EDTA. The homogenate was centrifuged at $15000 \times g$ for 15 min. All operation was performed at 4 °C. The supernatant was used for SOD (EC 1.15.1.1) activity [Giannopolitis and Ries 1977]. Reaction mixture (3 ml) consisted of 50 mM HEPES-KOH buffer (pH 7.8), 0.1 mM EDTA, 50 mM Na₂CO₃ (pH 10.2), 12 mM L-methionine, 75 μ M NBT, 300 μ L enzyme extract and 1 μ M riboflavin. One unit SOD activity was defined as the amount of enzyme required to result in a 50% inhibition of the rate of NBT reduction measured at 560 nm. Activity of CAT (EC 1.11.1.6) was measured in a reaction mixture containing 25 mM Na-phosphate buffer (pH 6.8), 10 mM H₂O₂ and enzyme extract in a total volume of 1 mL. The decomposition of H₂O₂ was followed by the decline in absorbance at 240 nm [Cakmak and Horst 1991]. In brief, samples were homogenized in 1 mL of 50 mM Na-phosphate buffer (pH 7.8) containing 5 mM ascorbate, 5 mM DTT, 5 mM EDTA, 100 mM NaCl and 2% (W/V) PVP. The homogenate was centrifuged at $15000 \times g$ for 15 min at 4 °C. The reaction was initiated by adding H₂O₂ to a final concentration of 44 μ M. The reaction rate was monitored by the decrease in absorbance at 290 nm. The rate constant was calculated using the extinction coefficient of 2.8 mM⁻¹ cm⁻¹ and corrected for the rate obtained prior to the addition of H₂O₂. The protein contents were determined by the method of Bradford [1976], using bovine serum albumin (BSA) as standard. All experiments were repeated with at least three independent repetitions and all data were expressed as the mean values \pm standard deviation (SD). The Statistical analysis was performed using student's t-test at $p < 0.05$ significant level of the difference.

The results showed that the exposure of the magnetic field caused an increase in the antioxidant enzymes activity (SOD & CAT) on the treatment cells (n=24) compared with the controls (n=24). The obtained average for enzymes activity of SOD on treatment group was 0.88 ± 0.01 (nm/mg. protein) while the obtained average for enzymes activity of SOD on control group was 0.55 ± 0.02 (nm/mg. protein) (Fig.2). Similarly, the best obtained average for enzymes activity of CAT on treatment group was 296.61 ± 122.87 (nm/mg. protein) while the best obtained average for enzymes activity of CAT on control group was 162.72 ± 24.06 (nm/mg. protein) (Fig. 3). The average results for the enzymatic antioxidative activity of SOD and CAT for treatment as well as control in two intensities of 10 and 30 mT were presented in table 1. These results showed that the activity of SOD in tobacco cells has been increased for both intensities (10 and 30 mT) in treatment cells. In contrast the activity of CAT showed a significant decrease in treatment cells compared with control. Our results showed significant difference of enzymes activity in treatment and control cells for SOD (two-tailed $p < 0.05$) and CAT (two-tailed $p < 0.03$) at 30 mT. Similarly, the enzymes activity in treatment and control cells for SOD

(two-tailed $p < 0.04$) and CAT (two-tailed $p < 0.01$) at 10 mT showed a significant difference. Regardless of enzyme activity obtained for CAT which show a bigger difference at 30 mT compared to 10 mT (fig3), there was not reasonable difference of enzyme activity for SOD as far as the intensity is concern (fig2). These results show that the enzymes activity is not directly dependent to intensity at these two selected intensity of 10 and 30 mT.

Summary

In recent years, the results of experimental studies have revealed that magnetic fields of moderate amplitudes ($B=1\text{--}100\text{mT}$) may alter the activity of certain enzyme reactions. An interpretation of the magnetic field activity observed in the enzyme reactions is based on the radical pair mechanisms [Zmyslony et al. 2000]. We actually tried 10 and 30mT in the initial stage of our *in vivo* experiment because these strengths are in the range that humans most often experience in our daily lives [Li and Chow 2001]. Compared to the pervious works which dealing with alternative current (AC) we assume that the effect of static magnetic field using DC current on enzymes activity is more severe. This is justifying because the cycle of 50HZ takes 20ms and the lifetime of a radical pair encounter is no longer than a few microseconds. It is therefore clear that the radical pairs may be affected for a long and continuous time interval by the static magnetic field [Zmyslony et al. 2000]. This may extend the life time of the free radical and its potential damage could be exaggerated.

Plants have several antioxidant enzymes and metabolites located in different plant cell compartments, the main ones being SODs a family metalloenzymes that convert O_2^\cdot to H_2O_2 . Because superoxide is the first product of univalent reduction of oxygen, SOD is considered as the “primary defense” against oxygen radicals [Banister et al. 1989]. The product of SOD, hydrogen peroxide, requires further detoxification. This is achieved by other enzymes and non-enzymatic antioxidants that may differ among the various cellular compartments. H_2O_2 is reduced to water by ascorbate peroxidase (APX). This enzyme uses a large pool of 10mM ascorbate present in the chloroplast and oxidizes it to monodehydroascorbate [Noctor and Foyer 1998]. Also, catalases (CATs) which are tetrameric heme-containing enzymes that similarly catalyze the removal of H_2O_2 [Willekens et al. 1995]. Changes in catalase in response to other stress conditions have also previously been reported. Willekens and coworker studied the three isoenzymes of catalases in response to environmental challenges such as UV-B, O_3 , and SO_2 [Willekens et al. 1995]. As a consequence of its sensitivity to environmental conditions, early loss of catalase was suggested as a signal for antioxidant defenses stimulus [Feierabend et al. 1996]. In a similar way, we tried the effect of the exposing to the SMF as another physical stress on catalase inhibition to investigate whether it can mediate defenses in tobacco cells or not.

In our study, a statistically significant CAT activity decrease was observed. Such a condition may indicate abnormal function of the antioxidant system caused by SMF which can lead to a high concentration of H_2O_2 in the cells. This incensement in H_2O_2 can cause a toxic condition. Spychalla and Desborough [1990] emphasized that the overproduction of the H_2O_2 -generating SOD must always be combined with increased levels of H_2O_2 -metabolizing catalase and/or peroxidase. Such combination can generate a powerful scavenging of toxic oxygen forms. On the contrary, an increase in SOD activity alone might enhance cytotoxicity by active oxygen species likely owing to the accelerated H_2O_2 generation and subsequent OH^\cdot overproduction by the metal catalyzed Haber-Weiss reaction [Piacentini et al. 2001]. Indeed, H_2O_2 accumulation may itself lead to higher active oxygen species (AOS) production [Spychalla and Desborough 1990]. The inconsistent action SOD and CAT enzymes as happened in our study due to the exposing to the static magnetic field contributes to increase the deteriorate effect of H_2O_2 and above all the risk of OH^\cdot formation, the decrease survival and the appearance of signs of senescence. This could be happened through reactivating few oxygen species that cause change vital functions. As a result we can consider that tobacco cells may efficiently metabolize superoxide but may have difficulties in eliminating the hydrogen peroxide when exposing to SMF. Evidence is reviewed here showing that SMF can increase free radicals and alter enzyme reactions which could highlight the activity of oxidant radicals.

Although formed in normal cell metabolism, free radicals are potentially damaging and can initiate chain reactions to form new free radicals. A main protective role against free radicals is attributed to SOD in catalyzing and dismutation of superoxide anions to O_2 and H_2O_2 (Sreenivasulu et al., 2000). The activity of SOD increased from 0.05 ± 0.004 to 0.09 ± 0.005 in 10 mT and from 0.07 ± 0.002 to 0.11 ± 0.006 in 30 mT MF treatments. It means that exposure to MF caused increases by 74% and 87% in unit of SOD activity in 10 and 30 mT-treated tobacco cells, respectively. It implies the first step of the increased production of free radicals by MF in tobacco cells. An increase in SOD activity might enhance cytotoxicity by active oxygen species likely owing to the accelerated H_2O_2 generation and subsequent OH^\cdot overproduction by the metal catalyzed Haber-Weiss reaction (Piacentini et al. 2001). Likewise, the activity of CAT was also reduced from 247 ± 15 to 146 ± 8 in 10 mT and from 264 ± 37 to 80 ± 11 in 30 mT MF treatments. Interestingly, the ratio of the reduction of CAT activity in 30 mT-treated cells was remarkably more than those treated with MF of 10 mT (70% versus 41%). Further experiments involving exposure of cells for a different time and at various magnetic field flux densities make it possible to establish threshold values for this biological effect [Jajte et al. 2001].

Abstract: The large number of radio frequency (RF) transmitters employed in combat systems of modern Naval surface combatants requires that they operate in mutual coexistence while posing no danger to operators and equipment despite the limited available physical space. A key to the successful combat system integration is the control of the electromagnetic environment on the combatants' topsides, which might pose radiation hazards (RADHAZ) to personnel (HERP). HERP are caused by transmitter antenna installations that generate intentional EM radiation in excess of the safe levels in zones of personnel activity. Radiation safety to personnel is achieved when the average radiation power density is below the permissible exposure limits (PEL) for HERP at locations of personnel activity and medical equipment operation. This paper describes the analysis tools and techniques for the evaluation of HERP on surface combatants. The same approaches could be employed in the analysis of land site antenna deployment scenarios.

Introduction

Modern surface naval combatants employ a vast array of electronic systems in order to accomplish their warfare missions. Toward this end, electronic systems utilized in combatants comprise powerful transmitters, some of which are broadband such as radar and ECM systems. These systems operate at frequencies from HF to Ka-band in order to perform an assortment of tasks: data and voice communications, radar search and track operations, fire control and weapon guidance activity, electronic warfare, etc.

As the electromagnetic radiation (EMR) sources on combatants' topsides are confined to extremely limited space on the combatants' topsides, they might compromise the EMR safety. Therefore, the EM environment on combatant topsides has to be controlled by either the proper placement of the effectors (hard solutions) or/and by establishing suitable system operational procedures (soft solutions).

RADHAZ are caused by transmitter antenna installations that generate intentional EMR in excess of safe levels in zones of personnel activity, ordnance storage and handling regions, or fueling operations areas. Correspondingly, RADHAZ is categorized according to the following three major groups of hazards of EMR to:

- Personnel (HERP) - harmful effects to humans,
- Ordnance (HERO) – initiation of electro-explosive devices by induced currents,
- Fuel (HERF) – ignition of flammable atmosphere–fuel vapors mixed with air.

In the context of EMR hazard to personnel, HERO and HERF pose indirect hazard; therefore, they will not be discussed.

It follows that during the process of combatant topsides integration, the electromagnetic compatibility (EMC) engineering should address HERP issues by controlling the EM environment, by design. EM Safety is achieved when either all the EMR levels onboard the ship are below the HERP PEL's at topside test point (TP) locations where personnel activity takes place.

From the engineering point of view, the analysis of the EM environment on the combatant topsides should reflect "worst case scenarios". Due to its complexity, combatant topside design is performed by means of computer analysis tools. The methods utilized in the software for topside EM analysis are discussed herein.

Topside EMR and Its Control

The potential for sustained HERP related problems on combatant topsides is due to the high level of EM energy emitted by the onboard intentional topside communications and combat system transmitters. Consequently, the EM environment on the topsides of surface combatants is the aggregate of a variety of RF components of time periodic EMR characterized by either modulated continuous wave (CW) (time harmonic), or repeated pulse (pulse train) modulated EM waves of period T within the range of 1.6 MHz to 36 GHz. Both the CW and pulsed modulated EMR represent finite bandwidth signals having approximate power spectral density (PSD) of similar shape ([1]).

Generally, EMR can be classified into one of the following two categories: ionizing radiation, and non-ionizing radiation. This classification is based on whether the EMR is capable of ionizing atoms and breaking chemical bonds. The EM environments onboard combatants is non-ionizing; thus, its biological effect is to cause dielectric heating. Consequently, the basic interaction of EMR with human tissue is by absorption of the EM energy. Exposure of humans to intense fields produces increased heating whose deposition in the tissue can lead to effects ranging from discomfort, through burns, to protein denaturation. As the human body does not have internal sensors for the sensation of heat, a major source of HERP danger is when the body absorbs

excess radiation, the awareness of the exposed individual. Consequently, as the victim does not feel the need to evacuate the RADHAZ area; thereby, the chance to biological damage increases due to the inability of the victim's body to dissipate the excess heat. Furthermore, strong EMF's induce electric currents in metal objects. The induced currents can cause RF burns or even electric shock to personnel whenever they touch surfaces of high current while standing on the "grounded" deck.

Combatants constitute an environment where personnel are aware of the potential danger of RF exposure associated concurrently with either their routine activity, or incidental transient passage through an area of high EMF. Accordingly, the regulations specifying acceptable limits of EMR exposures in such circumstances are lax as compared to those established for general public environments. Nevertheless, the corresponding RADHAZ permissible exposure limits (PEL's) serve as requirements for certification of combatants. HERP regulations are being regularly updated with the advance of the complex effects of EMR on the human body.

The current industrial specifications for HERP, contained in [1], were used as reference to create the combined HERP regulations for combatants. The resulting frequency dependent PEL's are based on a safety factor of ten over the specific absorption rate (SAR), which might cause bodily harm to humans at each EMR frequency. The graphs in **Figure 1** specify the PEL's for personnel, in terms of the electric field (E-field) strength, for both public and occupational exposure in accordance with [1].

Figure 1 Permissible Exposure Standard for Personnel, IEEE Standard C95.1, 2005

Nevertheless, exceptions to the maximum limits specified in **Figures 1** which allow higher EMR levels do exist ([1]). For example, the power density is allowed to violate the PEL in case of pulsed RF fields, while for cases in which the source is a rotator the power considered for HERP (only!) is reduced according to the following rule:

$$PEL_{scan}(f) = PEL_{fixed}(f) \frac{2 \times \text{Beam Width}}{\text{Scan Angle}} \quad (1)$$

where, f is the frequency of the EMR.

Computational EM (CEM) in Topside RADHAZ Analysis

The estimation of HERP from crowded multiple antenna sites can be performed either graphically ([2]), or purely computationally ([3], [4]) based on the following rule ([1], [2]):

$$\left(\frac{E_1}{E_{s1}}\right)^2 + \left(\frac{E_2}{E_{s2}}\right)^2 + \dots + \left(\frac{E_N}{E_{sN}}\right)^2 < 1 \quad (2)$$

where, E_1, E_2, \dots, E_N , are the E-field strength levels for the frequencies f_1, f_2, \dots, f_N , respectively, and $E_{s1}, E_{s2}, \dots, E_{sN}$ are the PEL's for the frequencies f_1, f_2, \dots, f_N , respectively. The application of Equation (2) requires the knowledge of the EMF strength or power received at various topside locations from the onboard transmitters. These are obtained via computer-aided predictions based on mathematical models of the topside HERP problem.

Mathematically, the HERP problem is expressed as a radiation/scattering field problem defined over an unbounded domain. However, due to the complexity of the conducting structures, closed form solutions of the topside integration problem are not accessible nor can they be generated using a single method. Thus, topside HERP analyses utilize an array of mathematical methods each suitable to the solution of a different aspect of the topside EMR problem. Due to the complexity of the domain of the topside integration problem, its solution is performed with the aid of numerical analysis tools executed on powerful computers.

Analysis of Radiation Hazards to Personnel on Surface Combatants

The prevalent approach practiced in engineering analysis favors the investigation of the behavior of dynamical systems in the frequency domain (FD) over the time domain (TD). The key to the selection of a suitable FD numerical method is the electrical size of the problem, defined as the ratio of the physical size of the conducting structure to the wavelength, $\lambda \approx 300/f$, of the radiated RF carrier wave where, f is in MHz. At low RF frequencies, the EM wavelengths are of the order of magnitude of the dimensions of the conductor; thus, they interact with it strongly by exciting global resonances; at high RF frequencies, the interactions between the various parts of the conductor are weak; consequently, parts of the structures remote to the RF source location act as scatterers of EMR (i.e., they reflect and diffract the EM waves).

The starting point of all CEM methods are the TD linear Maxwell's curl equations (partial differential equations). The FD CEM methods use the FD version of Maxwell's equations after assuming separation of the time and space dependent variables in conjunction with time-harmonic response postulation. FD CEM methods applied to combatant topside scattering problems are classified according to their FD applicability to the RADHAZ problem as follows:

- Numerical Methods – applied to low frequency analysis,
- Analytically Based Methods – for high frequency analysis.

FD numerical methods belong mostly to the methods known as direct numerical methods. These methods use approximate discrete expressions (interpolations) of the solution functions. The analytically based methods on the other hand, use closed form models (formulae) of wave front propagation (reflection, refraction, and diffraction) in order to calculate EMR fields from EM sources in the presence of scatterers.

In light of the wide range of frequencies of interest in topside RADHAZ analysis in conjunction with the conductor size, the applicability of numerical methods to combatant topside analysis is generally limited to the HF and low VHF (LVHF) ranges ($f=2-88$ MHz). Consequently, the prediction of topside RADHAZ at UHF and up has to be performed by analytically based methods, as these methods have no applicability limitation in terms of conductor and domain sizes, and the frequency of the source.

Numerical Analysis

Within the framework of the FD modeling of scatterers in unbounded domains, the most popular direct numerical method is known as the method of moments (MoM) ([3]). The method, whose major advantage is the circumvention of the need to model the surrounding non-conducting space, is based on the premise that the total electric field, E^t , at any point in space is the sum of the incident and the scattered electric fields. Furthermore, it assumes that the E-field scattered from metallic surfaces is produced by currents induced in the scatterer by the incident field such that the total tangential E-field on its surfaces vanishes (a boundary condition with the unbounded free space); i.e., $E^t = E^s + E^i = 0$. Hence, MoM is a CEM method that uses a specialized analytical solution of Maxwell's equations.

The application of MoM to real conducting structures is accomplished by representing the conducting surfaces of the scatterer as a fine mesh of M thin cylindrical conducting wires of radii a . Consequently, the complete structure can be represented as the sum of the contributions of M wires assuming that their currents are compatible at the nodes of the mesh. Subsequently, the mathematical model, in the sense of MoM, is a system of linear algebraic equations of the general form:

$$[Z]\{I\} = \{E\} \quad (3)$$

where, $[Z]$ is the global impedance matrix, $\{I\}$ is the unknown global current vector, and $\{E\}$ is the excitation vector.

The impedance matrix in Equation (3) is full rank. It is solved either by means of LU decomposition, or by a more efficient nonlinear programming method such as the conjugate gradient method ([5]). Once the M wire currents are known, the E-field at any TP on the topside can be calculated from the definition of the potential vector A :

$$E^s(r) = -j \frac{2\pi}{f} \left[A + j \frac{1}{\mu\epsilon} \nabla(\nabla \cdot A) \right] \quad (4)$$

Analytically Based Methods

The solutions obtained via the analytically based methods (also known as semi-analytical methods) are valid for high EMR frequencies in the sense that the EM waves are well formed and locally planar with respect to the conducting structure. It can be inferred that for scatterer sizes larger than two wavelengths, ray-tracing techniques can be utilized in order to calculate the fraction of the EM power reaching topside TP's from topside sources in the presence of scattering obstacles. In order to obtain realistic predictions of the levels of radiation at specified locations, the following source and propagation parameters, among others, should be considered:

- The radiation pattern of each transmitting antenna,
- The near-field (Fresnel Zone) boundaries and intensities,

- Antenna polarization, and cross polarization,
- In-band, out-of-band antenna performance,
- Blockage of line of sight by metallic structural components,
- Presence of radiation absorbing materials (RAM).

The (far-field) pattern of EMR from wanted topside radiation sources is either omni-directional, or directional as depicted in **Figure 2**. Far enough from the source the EMR propagates as a plane wave; nevertheless, often, the topside victims of the excessive radiation are positioned within the near-field regions of the topside sources, which are characterized, irregular field intensities.

Figure 2 – Omni (left), and Directional (right) Radiation Pattern

The calculations of transmission losses of EMR power density due to propagation from topside sources to TP's follows Friis' modeling. Accordingly, the power density, Φ_D , received at a TP located a distance r from a Tx antenna is given by ([4]):

$$\Phi_D = \frac{P_T G_T}{4\pi r^2 L_F} \quad (5)$$

Where, P_t is the transmitted power, G_T is the (far-field) gain of the Tx antenna, which is a metric characterizing the directivity, $D=4\pi/\Omega_b$ (Ω_b is the 3-dB beam solid angle), and L_F is a path loss factor. Subsequently, the power received at the victim location is just given by $P_R = A_{eff} \Phi_D$ where, A_{eff} is the effective receiving area.

As distances between the EMR sources and victim TP are relatively small for the topside RADHAZ problem, atmospheric propagation losses are negligible. Consequently, the path loss factor is determined by the extent of physical blockage along the line of sight (LoS) between the source and the victim. **Figure 3** (left) shows the possible paths and geometries of EM rays emanating from a generic point source to various observation positions in the presence of a wedge scatterer ([8]). As indicated in **Figure 3** (left), three radiation zones can be identified around the obstacle: direct/reflection/diffraction zone, direct/diffraction zone, and diffraction only zone.

Figure 3 EMR Past a Wedge (left), and Wedge Diffraction (right)

Accordingly, diffraction coefficients are calculated based on the uniform/geometric theory of diffraction (U/GTD). The parameters determining the values of the diffraction coefficients are mainly:

- The incident and diffracted ray angels (found by ray tracing),
- The wave frequency and polarization,
- The wedge angle (where applicable).

A simple analytic GTD expression for wedge diffraction of tip angle $(2-n)\pi$ (n being some real number) is given by ([8]):

$$D_{e_m} = \frac{\sin(\frac{\pi}{n})}{2\pi n (\frac{f}{300})^2} \left(\left[\cos\left(\frac{\pi}{n}\right) - \cos\left(\frac{\phi-\phi'}{n}\right) \right]^{-1} \mp \left[\cos\left(\frac{\pi}{n}\right) - \cos\left(\frac{\phi+\phi'}{n}\right) \right]^{-1} \right) \quad (6)$$

With the incident and diffracted angles indicated in **Figure 3** (right).

Modeling of the Topside RADHAZ Problem

The application of FD methods to the topside EMR problem requires the modeling of EM sources, EMR propagation, and scatterers. The modeling procedure corresponding to the application of both MoM and UTD to RADHAZ analysis is described herein.

Topside transmitting antennas are the sources of the intentional EMR components comprising the topside EM environment. In order to analyze the topside RADHAZ they have to be modeled over the entire RF range. Generally, in MoM analysis the models of sources are constructed to “reproduce” the physics of the real device, whereas in the case of the analytically based methods the models merely reflect the device typical operational characteristics. Once the models of the source of EMR are established, the propagation loss of the radiation from sources to observer (test) points in the presence of scatterers has to be ascertained.

MoM Modeling

Low frequency topside antennas are sources of E-fields. The modeling of E-field sources is implemented by inserting a gap of infinitesimal length at the midpoint of a wire located at the position in the wire model corresponding to the real source location and assigning an E-field across it. **Figure 4** depicts the current distribution and the radiation pattern of a 10-wire lineal structure (antenna) radiating in free space in response to a 20 MHz source located at its bottom wire.

Figure 4 – 10-Wire Model of Monopole Free Space Antenna: Current Distribution (left), Radiation Pattern (right) at 20 MHz

MoM is based on first principles of physics, the correctness of their solutions is indisputable. However, in order to reduce numerical dispersion effects on the approximate solution the use of at least ten sample points within a wavelength is required. Consequently, the maximum length of the longest wire in the model is required to be $L=0.1\lambda$, at least. Furthermore, the successful application of the MoM requires that the network of wires representing the conducting structure (including all the topside antennas) follow a specific set of modeling restrictions in order to keep the modeling errors within the engineering acceptable range (a few percent). Furthermore, the ship structure from the waterline up has to be modeled in order to avoid the generation of spurious modes corresponding to any arbitrarily imposed boundaries. An example of a wire mesh model is shown in **Figure 5** for a nominal design of a 50m ship. The model discretizes the ship outer surfaces all the way to the waterline using 6,758 wires. The surface of the water is represented as an infinite ground plane having seawater permittivity and conductivity.

Figure 5. MoM Discretization of a Nominal Combatant and the Radiation Pattern Of a HF Whip Antenna at 20 MHz

The frequency limitation on the applicability of the MoM is due to its inherent disadvantage that the memory requirement for the discrete model depends quadratically on the size of the conducting structure, while the computational complexity depends on the sixth power of the source frequency. This leads to high computational costs both in terms of computer resources and computation time. Furthermore, as the increase of frequency leads to a numerical model whose spatial resolution exceeds the geometrical confidence level of the design.

Analytically Based Methods Modeling

The limitation of the applicability of the numerical methods to low frequency analyses, requires supplemental methods for handling high frequencies (UHF and up for ships). The idea is to take advantage of the small wavelength relative to the scattering structure in order to generate analytical models that follow geometric arguments.

The general radiation pattern from an EMR source (antenna) is characterized by the presence of a main beam shaped to deliver RF energy along its axis. Nevertheless, due to local diffraction effects, sidelobes and backlobes regions exist as well as depicted

in **Figure 6** (left). Normally the spurious regions show a reduction of 10 dB from mainlobe gain in conjunction with half the beamwidth.

Figure 6 – Simplified Model of Antenna Radiation Patterns

The radiation pattern can be characterized by various analytical approaches. Nonetheless, satisfactory results are also obtained via simplified models based on physical arguments. Accordingly, radiation patterns are classified according to their EM properties via the notion of the antenna gain of the radiation pattern and the effect of its impedance mismatch. Consequently, it is possible to determine the radiation pattern parameters of topside antennas using merely three necessary input parameters: the directional mainlobe gain ($G_0 = \eta D$, η radiation efficiency), the azimuth 3dB beamwidth angle (α), and the elevation 3dB beamwidth angle (β) as shown in **Figure 6** (right).

Nevertheless, as often the EMR field at the near-field of the antenna is of interest, the above far field models are corrected to account for near-field EMR. In addition, in order to account for nonlinear effects, empirical harmonic order correction factors for both CW and pulsed transmitter harmonic order attenuations are available.

Due to proximity of the topside transmitters to locations where personnel activity and/or mission critical equipment operate, it is important to consider the location of the near-field border (the point in which a planar wave front is received) corresponding to each topside emitter. The near-field/far-field border location, R_{FF} is determined according to [7] for the two antenna groups:

$$R_{FF} = \begin{cases} 5\lambda & \text{for lineal antennas} \\ \frac{2D^2}{\lambda} & \text{for 2D and 3D aperture antennas} \end{cases} \quad (7)$$

where, D is the maximal linear dimension of the aperture, and λ is the wavelength. Calculating the “near-field correction”, there are different models for three groups of antennas: reflector-aperture antennas, horn-aperture antennas, and lineal antennas.

As the high frequency methods are formulated based on the application of formulae, these methods offer low computational cost both in terms of computing time and machine resources.

Summary

In light of the complexity of topside configurations of modern surface combatants, analysis of topside EM environment is mandatory in order to assure the safety and functionality of the platform. Topside HERP analysis is based on the CEM prediction of EMR levels on the topside. Due to the large physical size of combatants and the wide frequency range employed by their combat systems, topside EMR analysis requires the employment of both low frequency methods, consisting of numerical analysis methods based on MoM, and high frequency methods that are based on ray-tracing algorithms in conjunction with analytically derived formulae. The latter offers high computational efficiency while the former provides accurate physical modeling requiring significant computational resources. HERP safety is achieved as a combination of adequate antenna placement and operating procedures.

THEORETICAL ANALYSIS OF VOLTAGE INDUCEMENT ON ORGANELLE MEMBRANES

TADEJ KOTNIK and DAMIJAN MIKLAVČIČ

UNIVERSITY OF LJUBLJANA, FACULTY OF ELECTRICAL ENGINEERING,
TRŽAŠKA 25, SI-1000 LJUBLJANA, SLOVENIA

Abstract

Several reports have recently been published on effects of very short and intense electric pulses on cellular organelles; in a number of cases, the cell plasma membrane appeared to be affected less than certain organelle membranes, while with longer and less intense pulses the opposite is the case. The effects are the consequence of the voltages induced on the membranes, and in this paper we investigate the conditions under which the induced voltage on an organelle membrane could exceed its counterpart on the cell membrane. This would provide a possible explanation of the observed effects of very short pulses.

Frequency-domain analysis yields an insight into the dependence of the voltage inducement on the electric and geometric parameters characterizing the cell and its vicinity. The calculations show that at sufficiently high field frequencies, for a range of parameter values the voltage induced on the organelle membrane can indeed exceed the voltage induced on the cell membrane. Particularly, this can occur if the organelle interior is electrically more conductive than the cytosol, or if the organelle membrane has a lower dielectric permittivity than the cell membrane, and we discuss the plausibility of these conditions.

Time-domain analysis is then used to determine the courses of the voltage induced on the membranes by pulses with risetimes and durations in the nanosecond range. The particularly high resting voltage in mitochondria, to which the induced voltage superimposes, could contribute to the explanation why these organelles are the primary target of many observed effects.

1. INTRODUCTION

An exposure of a biological cell to an electric field of sufficient strength can lead to a significant increase in the permeability of the cell plasma membrane (40). If such an exposure is neither too strong nor too long, this phenomenon — referred to as *electroporation* or *electropermeabilization* — is reversible. This allows many otherwise nonpermeant molecules to enter into the cytosol or be inserted into the plasma membrane. Due to its efficiency, electroporation is rapidly becoming an established approach for treatment of solid cutaneous and subcutaneous tumors (22, 47), and it also holds great promise for gene therapy (17).

The mechanism underlying electroporation is the inducement of a voltage on the cell plasma membrane. This voltage is proportional to the field strength and superimposes onto the resting voltage present on the membrane under physiological conditions, typically about -70 mV (37). According to the theory of electroporation, a voltage on the membrane reduces the energy necessary for rearrangements of the membrane lipids that result in formation of aqueous passages (hydrophilic pores) and consequently in increased conductivity and permeability of the membrane. Consequently, as the voltage increases, so does the probability of formation of such passages. The resting voltages normally present on the cell membrane and on the organelle membranes — the largest is in mitochondria, about -140 mV (1) — are insufficient for this, and electroporation is not observed physiologically. However, with exposures to electric fields inducing voltages of several hundreds of millivolts, electroporation of the cell membrane becomes readily achievable and observed in experiments. Both the theory of electroporation (57, 41) and recent computational studies based on molecular dynamics (52, 53, 50) corroborate that as the membrane voltage increases, so does the rate of formation of metastable aqueous passages in the membrane.

The fields used for electroporation are most often delivered as rectangular pulses, with typical amplitudes of several hundred volts per centimeter, durations from tens of microseconds to milliseconds, and risetimes in microseconds. In the first few microseconds after the onset of the pulse, such exposures induce a voltage in the range of several hundred mV on the cell membrane, and this voltage persists until the end of the pulse. Also within microseconds, this leads to the onset of electroporation, detected as a steep increase in electrical conductivity and permeability of the membrane (24, 25).

The exposure of a cell to an electric field also induces voltages on the organelle membranes in the cell interior, but in their steady state, these are several orders of magnitude smaller than the voltage induced on the cell membrane. Thus when the cell membrane is electroporated with typical electroporation pulses with durations of hundreds of microseconds or several milliseconds, the organelle membranes are left unaffected. However, in a number of recent papers it has been reported that with much stronger (typically tens or hundreds of thousands of volts per centimeter) but much shorter (typically tens or hundreds of nanoseconds) pulses, the situation seems to be reversed, with the cell membrane affected less than some internal cell structures (46, 11, 7, 10, 19, 51). In many cases, a mitochondria-dependent apoptosis was observed, which could be due to electroporation of these organelles (6, 8, 58). For brevity, the high-intensity, nanosecond-duration pulses used in these experiments are often referred to as nsPEF (nanosecond-duration pulsed electric fields), and we will also adopt this practice here.

In this paper we explore one possible explanation of the observed effects of nsPEF on intracellular membranes. As discussed above, the steady-state value of the voltage induced on the cell membrane is always much larger than its counterpart on an organelle membrane. But the pulses with durations in the submicrosecond range are too short for the two voltages to approach their steady states, and their time courses become important. These depend on a number of geometric and electric parameters, and here we investigate whether there is a range of plausible parameter values for which the voltage on an organelle membrane can temporarily exceed the voltage on the cell membrane. This explanation has been proposed before, based on considerations of a more qualitative nature (46) and later on finite-elements modeling (29). Here, we derive analytical expressions for the induced voltages and analyze the role of each parameter. In Section 2 we present the expressions for the induced voltages, and in Section 3 we analyze the dependence of these voltages on each of the parameters.

2. DERIVATION OF THE INDUCED VOLTAGES

2.1 The model of a cell with an organelle

For a valid treatment of the membrane voltage induced by alternating fields with frequencies in the MHz and GHz range, or by pulsed fields with risetimes below 1 μ s, both the electric conductivities and the dielectric permittivities of the membranes and the surrounding aqueous media have to be taken into account. An analytical treatment of such a system is possible only if the cell is the only object distorting the uniform electric field, and only in geometries where all the boundaries can be expressed as coordinate surfaces. Throughout this work, we will treat a single spherical cell, which meets these requirements. A spherical cell with a uniform interior (i.e. containing no organelles) is widely used in theoretical studies of cells exposed to electric fields, e.g. in derivation of the Schwan equation (38, 31) and its extensions (18, 32, 33, 34). The model with an organelle is then obtained by incorporating into the cell interior another spherical body with a concentric shell. This model (Fig. 1) consists of five regions, each characterized by an electric conductivity (σ , in S/m) and a dielectric permittivity (ϵ , in As/Vm). From the center outwards, the regions are the organelle interior (subscript 1i), the organelle membrane (1m), the cytosol (2i), the cell plasma membrane (2m), and the cell exterior (e). The radii of the organelle and the cell are denoted by R_1 and R_2 , and their membrane thicknesses by d_1 and d_2 . Although simplistic, this model is adequate for analyzing the voltages induced on the cell membrane and on organelle membranes (13, 29).

The spatial distribution of the electric potential in and around a spherical cell exposed to a uniform electric field is obtained by solving the Laplace equation in spherical coordinates (39). In each of the five regions of the model shown in Fig. 1, it has the general form

$$\Psi(r, \theta) = \left(A_k r + \frac{B_k}{r^2} \right) \cos \theta, \quad (1)$$

with r the radius measured from the center, θ the angle with respect to the direction of the field, and with constants A_k and B_k specific for each regions. Finiteness of the electric potential at $r = 0$ implies $B_{1i} = 0$, and from uniformity of the field at $r \rightarrow \infty$ it follows that $A_e = -E$. The remaining constants A_{1i} , A_{1m} , B_{1m} , A_{2i} , B_{2i} , A_{2m} , B_{2m} , and B_e are determined by the requirement of continuity of the potential, Ψ , and of the normal component of the current density, $\Lambda(\partial\Psi/\partial r)$, at all four boundaries between the regions. In frequency-domain (FD) analysis, Λ is the complex

Figure 1

conductivity (admittivity), $\sigma + j\omega\epsilon$, where ω is the angular frequency of the field, and in time-domain (TD) analysis, it is the admittivity operator, $\sigma + \epsilon(\partial/\partial t)$, where $\partial/\partial t$ is the operator transforming a function into its time derivative. The continuity requirements for the boundary between the organelle membrane and the cytosol can be written as

$$\begin{aligned} A_{1m}r + \frac{B_{1m}}{r^2} &= A_{2i}r + \frac{B_{2i}}{r^2}, \\ \Lambda_{1m}\left(A_{1m} - \frac{2B_{1m}}{r^3}\right) &= \Lambda_{2i}\left(A_{2i} - \frac{2B_{2i}}{r^3}\right), \end{aligned} \quad (2)$$

where in the FD $\Lambda_{1m} = \sigma_{1m} + j\omega\epsilon_{1m}$, $\Lambda_{2i} = \sigma_{2i} + j\omega\epsilon_{2i}$, and in the TD $\Lambda_{1m} = \sigma_{1m} + \epsilon_{1m}(\partial/\partial t)$, $\Lambda_{2i} = \sigma_{2i} + \epsilon_{2i}(\partial/\partial t)$. Analogous pairs of conditions characterize the other three boundaries. The direct dealing with operators in the TD can be avoided by transferring the treatment into the complex-frequency space, as described in Section 2.3.

The solutions for the eight constants are relatively lengthy expressions, as in general each of them incorporates the geometric and electric parameters of all five regions of the model, but algebraically their determination is elementary, since they form a well-defined system of eight equations with eight unknowns. The derivation and the solutions for the spherical cell with an organelle as shown in Fig. 1 are available at the web address <http://www.biophysj.org/cgi/content/full/biophysj.105.070771/DC1>

Once all the constants are determined, the voltage induced on a membrane is determined as the difference between the potentials $\Psi(r, \theta)$ at the inner and outer surface of this membrane. For the voltage induced on the cell plasma membrane this yields

$$\Delta\Psi_{\text{cell}} = \frac{3ER_2d_2 \left[\begin{aligned} &\left((R_1 - d_1)^3 (\Lambda_{1i} - \Lambda_{1m}) \right) \left(\begin{aligned} &2(3R_2^2 - 3R_2d_2 + d_2^2) \left(\begin{aligned} &(R_2 - d_2)^3 (\Lambda_{1m} - \Lambda_{2i}) \\ &+ R_1^3 (2\Lambda_{1m} + \Lambda_{2i}) \end{aligned} \right) \Lambda_{2i} \\ &+ (3R_2d_2 - d_2^2) \left(\begin{aligned} &2(R_2 - d_2)^3 (\Lambda_{1m} - \Lambda_{2i}) \\ &- R_1^3 (2\Lambda_{1m} + \Lambda_{2i}) \end{aligned} \right) \Lambda_{2m} \end{aligned} \right) \Lambda_e \\ &+ R_1^3 (\Lambda_{1i} + 2\Lambda_{1m}) \left(\begin{aligned} &(3R_2^2 - 3R_2d_2 + d_2^2) \left(\begin{aligned} &(R_2 - d_2)^3 (\Lambda_{1m} + 2\Lambda_{2i}) \\ &+ 2R_1^3 (\Lambda_{1m} - \Lambda_{2i}) \end{aligned} \right) \Lambda_{2i} \\ &+ (3R_2d_2 - d_2^2) \left(\begin{aligned} &(R_2 - d_2)^3 (\Lambda_{1m} + 2\Lambda_{2i}) \\ &- R_1^3 (\Lambda_{1m} - \Lambda_{2i}) \end{aligned} \right) \Lambda_{2m} \end{aligned} \right) \end{aligned} \right] }{M} \cos\theta \quad (3)$$

and for the voltage induced on the organelle membrane

$$\Delta\Psi_{\text{org}} = \frac{27ER_1R_2^3d_1(R_2 - d_2)^3(3R_1^2\Lambda_{1i} - d_1(3R_1 - d_1)(\Lambda_{1i} - \Lambda_{1m}))\Lambda_{2i}\Lambda_{2m}\Lambda_e}{M} \cos\theta \quad (4)$$

where both in (3) and (4)

$$\begin{aligned} M = &2(R_1 - d_1)^3 (\Lambda_{1i} - \Lambda_{1m}) \left(\begin{aligned} &(R_2 - d_2)^3 (\Lambda_{1m} - \Lambda_{2i}) \left(\begin{aligned} &2(R_2 - d_2)^3 (\Lambda_{2i} - \Lambda_{2m})(\Lambda_{2m} - \Lambda_e) \\ &+ R_2^3 (\Lambda_{2i} + 2\Lambda_{2m})(\Lambda_{2m} + 2\Lambda_e) \end{aligned} \right) \\ &+ R_1^3 (2\Lambda_{1m} + \Lambda_{2i}) \left(\begin{aligned} &(R_2 - d_2)^3 (2\Lambda_{2i} + \Lambda_{2m})(\Lambda_{2m} - \Lambda_e) \\ &+ R_2^3 (\Lambda_{2i} - \Lambda_{2m})(\Lambda_{2m} + 2\Lambda_e) \end{aligned} \right) \end{aligned} \right) \\ &+ R_1^3 (\Lambda_{1i} + 2\Lambda_{1m}) \left(\begin{aligned} &(R_2 - d_2)^3 (\Lambda_{1m} + 2\Lambda_{2i}) \left(\begin{aligned} &2(R_2 - d_2)^3 (\Lambda_{2i} - \Lambda_{2m})(\Lambda_{2m} - \Lambda_e) \\ &+ R_2^3 (\Lambda_{2i} + 2\Lambda_{2m})(\Lambda_{2m} + 2\Lambda_e) \end{aligned} \right) \\ &+ 2R_1^3 (\Lambda_{1m} - \Lambda_{2i}) \left(\begin{aligned} &(R_2 - d_2)^3 (2\Lambda_{2i} + \Lambda_{2m})(\Lambda_{2m} - \Lambda_e) \\ &+ R_2^3 (\Lambda_{2i} - \Lambda_{2m})(\Lambda_{2m} + 2\Lambda_e) \end{aligned} \right) \end{aligned} \right) \end{aligned} \quad (5)$$

The substitution $\Lambda = \sigma + j\omega\epsilon$ for each of the five regions provides the starting point for analysis of $\Delta\Psi_{\text{cell}}$ and $\Delta\Psi_{\text{org}}$ in the FD, and the substitution $\Lambda = \sigma + \epsilon(\partial/\partial t)$ does the same for the TD.

2.2 Analysis in the frequency domain

The frequency domain (FD) is the natural setting for an exposure of a cell to a sinusoidal electric field. Fixing the geometric and electric parameters of the model, inserting for E the amplitude of the field, and writing explicitly $\Lambda = \sigma + j\omega\epsilon$, the induced voltages $\Delta\Psi_{\text{cell}}$ and $\Delta\Psi_{\text{org}}$ become functions of a single variable, namely ω , the angular frequency of the field. For a fixed ω , the values of $\Delta\Psi_{\text{cell}}$ and $\Delta\Psi_{\text{org}}$ are complex numbers, with $|\Delta\Psi_{\text{cell}}|$, $|\Delta\Psi_{\text{org}}|$ corresponding to the amplitudes of the induced voltages, and $\arg(\Delta\Psi_{\text{cell}})$, $\arg(\Delta\Psi_{\text{org}})$ to their phase shifts with respect to the external field. It should be emphasized that these values characterize the sinusoidal steady states that are established after the transients occurring at the onset of the field are over.

By considering $\Delta\Psi_{\text{cell}}$ and $\Delta\Psi_{\text{org}}$ as functions of ω , it is then determined very straightforwardly whether there is a range of parameter values and field frequencies where $\Delta\Psi_{\text{org}}$ can — at least temporarily — exceed $\Delta\Psi_{\text{cell}}$. The results of such analysis are presented in Section 3.1.

The approach described above can be extended to other periodic time courses of the field representable as uniformly convergent Fourier series. The induced voltages are then given by the series of voltage components induced by individual field components in the Fourier series.

2.3 Analysis in the time domain

The time domain (TD) is the natural setting for exposures of a cell to aperiodic fields, as well as to periodic fields for which the Fourier series is nonuniformly convergent.* This class clearly contains a rectangular and a trapezoidal (i.e. having non-zero risetime and falltime) pulse, but it also contains periodic trains of such pulses, as the uniform convergence requirement fails at the pulse edges, which is usually referred to as the Gibbs phenomenon (23). As mentioned in Section 2.1, the most convenient approach here is an interim transfer of the treatment to the complex-frequency space. Denoting the complex frequency by s , the differentiation with respect to time is thereby transformed into multiplication by s , and time courses are replaced by their Laplace transforms. Fixing again the geometric and electric parameters of the model, inserting for E the Laplace transform of the time course of the electric field, $L[E(t)] = E(s)$, and writing explicitly $\Lambda = \sigma + \epsilon s$, the expressions for $\Delta\Psi_{\text{cell}}$ and $\Delta\Psi_{\text{org}}$ become functions of s . The time courses of the induced voltages are then obtained as inverse Laplace transforms, $\Delta\Psi_{\text{cell}}(t) = L^{-1}[\Delta\Psi_{\text{cell}}(s)]$ and $\Delta\Psi_{\text{org}}(t) = L^{-1}[\Delta\Psi_{\text{org}}(s)]$. This yields the complete time courses, including the transients.

Provided that $E(s)$ is a polynomial in s , $\Delta\Psi_{\text{cell}}$ and $\Delta\Psi_{\text{org}}$ are rational functions (i.e. fractions of polynomials) of s , and the inverse Laplace transforms are obtained easily. The method is also applicable to all other cases for which the Laplace transform of $E(t)$ and the inverse Laplace transforms of $\Delta\Psi_{\text{cell}}$ and $\Delta\Psi_{\text{org}}$ can be obtained explicitly. For many of the conceivable time courses of the electric field, the transforms can be found in standard tables (43), while for other sufficiently regular functions they can be derived by means of the Laplace transform integral and the Bromwich integral, respectively (2). For more intricate cases, discretization of time and application of the unilateral Z-transform instead of the Laplace transform would yield approximate solutions.

3. RESULTS AND DISCUSSION

The aim of this paper is to evaluate the voltages induced by nsPEF, which will be approximated as having a trapezoidal shape. As described in the preceding sections, the natural setting for this is the TD, in which this aim will be pursued in Section 3.2. However, there are four geometric and ten electric parameters that have to be investigated with respect to their influence on $\Delta\Psi_{\text{cell}}$ and $\Delta\Psi_{\text{org}}$, and a trapezoidal pulse is characterized by a risetime, an amplitude, a duration pertaining to this amplitude, and a falltime. For a first insight into the role of the parameters, and for a selection of those to be investigated further, a clearer picture is provided by treating an exposure of a cell to a sinusoidal field, which is characterized only by its amplitude and frequency. Along these lines, Section 3.1 investigates the influence of each of the parameters in the FD, and a much smaller subset of parameters chosen on the basis of this investigation is then used in Section 3.2 in the TD with trapezoidal pulses.

* For other periodic fields, the analysis in the frequency domain is simpler, yet the analysis in time domain is nonetheless applicable, due to which it may be viewed as the more general of the two.

3.1 Voltages induced by a sinusoidal field

The purpose of this section is to determine whether in an exposure of a cell to a sinusoidal field, there is a range of parameter values for which $|\Delta\Psi_{\text{org}}|$ can exceed $|\Delta\Psi_{\text{cell}}|$, or equivalently, for which the ratio $|\Delta\Psi_{\text{org}}| / |\Delta\Psi_{\text{cell}}|$ can exceed the value of 1. The expressions for $\Delta\Psi_{\text{cell}}$ and $\Delta\Psi_{\text{org}}$ in Section 2.1 show that this ratio depends on practically all the geometric and electric parameters of the model. The only exceptions are σ_e and ϵ_e , as the numerators of $\Delta\Psi_{\text{cell}}$ and $\Delta\Psi_{\text{org}}$ are proportional to $\Lambda_e = \sigma_e + j\omega\epsilon_e$, while their denominators are identical, so that in the ratio $|\Delta\Psi_{\text{org}}| / |\Delta\Psi_{\text{cell}}|$ all occurrences of Λ_e cancel out. The simplest method for investigation of the role of the remaining twelve parameters is by means of parametric studies, in which one parameter is varied through a given range while the others are kept at their default values. Restriction to one variable at a time does not completely elucidate the behavior of a function of twelve variables, but the results of such parametric studies are easy to interpret, and will also suffice for the aims of this paper.

Table 1 gives the default values and variation ranges of the parameters. The default values are based on the typical data found in the literature, and the limits of the variation ranges were chosen as physically plausible values. For the reasons discussed above, σ_e and ϵ_e do not enter the parametric studies, for which the table gives only the default values, which are needed when the two voltages are of interest, and not only their ratio.

Table 1. Default values and variation ranges for parametric studies

Parameter	Default value	Variation range	Parameter	Default value	Variation range
σ_{1i} [S/m]	0.3 ^(a)	0.1 – 1.0	ϵ_{1i} [As/Vm]	6.4×10^{-10} ^(b)	$(3.5 - 7.0) \times 10^{-10}$
σ_{1m} [S/m]	3×10^{-7} ^(c)	$10^{-8} - 10^{-5}$	ϵ_{1m} [As/Vm]	4.4×10^{-11} ^(d)	$(1.8 - 8.8) \times 10^{-11}$
σ_{2i} [S/m]	0.3 ^(e)	0.1 – 1.0	ϵ_{2i} [As/Vm]	6.4×10^{-10} ^(b)	$(3.5 - 7.0) \times 10^{-10}$
σ_{2m} [S/m]	3×10^{-7} ^(f, g)	$10^{-8} - 10^{-6}$	ϵ_{2m} [As/Vm]	4.4×10^{-11} ^(g)	$(1.8 - 8.8) \times 10^{-11}$
σ_e [S/m]	1.2 ^(h)	—	ϵ_e [As/Vm]	6.4×10^{-10} ^(b)	—
R_1 [μm]	3	1 – 8	d_1 [nm]	5	3 – 15
R_2 [μm]	10	5 – 100	d_2 [nm]	5 ^(k)	3 – 7

Each of the parametric studies was performed for ω spanning the range from 10^5 to 10^{10} s^{-1} , yielding a set of data that can be visualized clearly in a contour plot of the ratio $|\Delta\Psi_{\text{org}}| / |\Delta\Psi_{\text{cell}}|$ as a function of frequency and the studied parameter. As shown in Figure 2, with the default values assigned to all parameters, this ratio does not exceed the value of 1 for any frequency. A similar result is obtained if the two membranes are assigned realistic dielectric permittivities but zero electric conductivities (13).

However, in eight of the twelve parametric studies, for sufficiently high frequencies the ratio $|\Delta\Psi_{\text{org}}| / |\Delta\Psi_{\text{cell}}|$ does exceed 1 in a certain range of parameter values. The contour plots showing the results of the parametric studies are given in Figure 3, from which two clear properties emerge. First, in the higher MHz range, either a small increase of σ_{1i} above its default value, or a small decrease of σ_{2i} below its default value suffices for $|\Delta\Psi_{\text{org}}|$ to exceed $|\Delta\Psi_{\text{cell}}|$. And second, in the higher MHz range and in the GHz range the same is the case for a decrease of ϵ_{1m} and for an increase of ϵ_{2m} . A more general

Figure 2

formulation is that the ratio $|\Delta\Psi_{\text{org}}| / |\Delta\Psi_{\text{cell}}|$ can exceed the value of 1 if the organelle interior has a higher electric conductivity than the cytosol, or if the organelle membrane has a lower dielectric permittivity than the cell membrane. The effect of $\sigma_{\text{li}} > \sigma_{\text{2i}}$ is due to the fact that with the increase of frequency, the shielding of the cell interior by the plasma membrane weakens, and the electric current flowing through the cell becomes concentrated in the organelle interior. The effect of $\epsilon_{\text{1m}} < \epsilon_{\text{2m}}$ is also easily explained, as the voltage inducement is faster on the membrane with the lower dielectric permittivity.

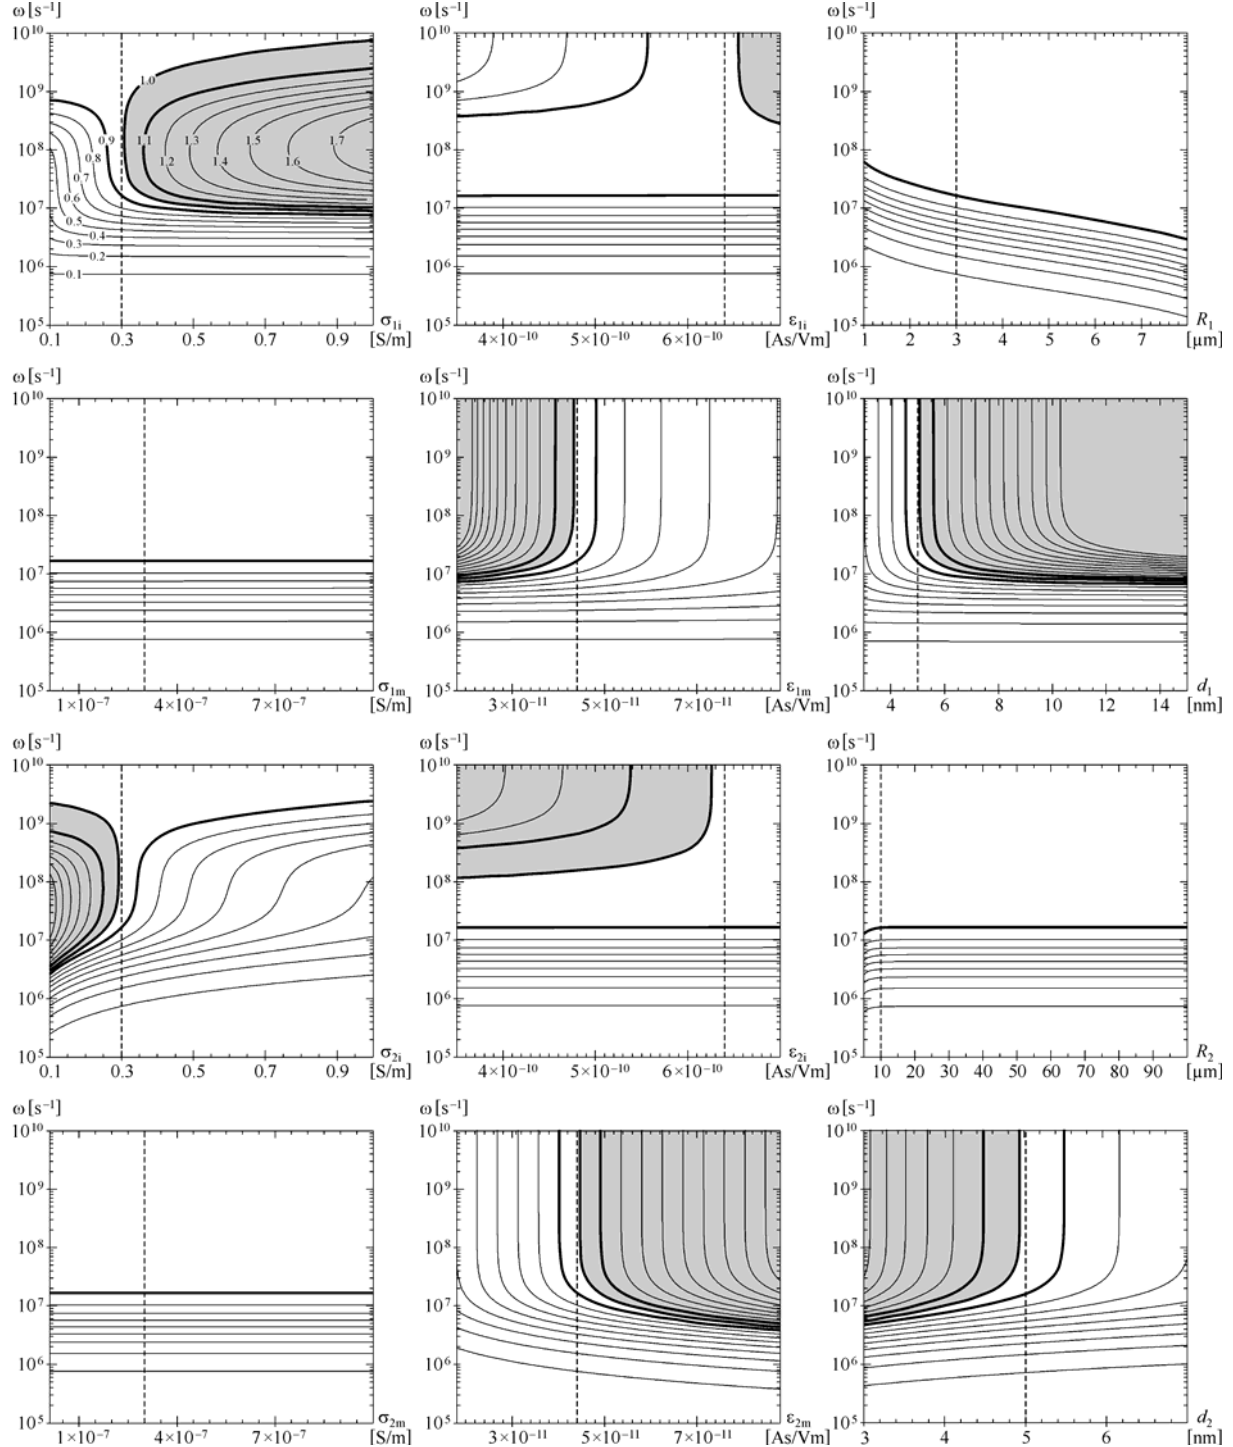

Figure 3

For $\sigma_{\text{li}} > \sigma_{\text{2i}}$, the organelle interior would have to contain either a higher total concentration of ions with respect to the cytosol, or a larger fraction of ions with higher mobility (e.g. more potassium and less sodium). In a recent computational analysis, the concentration of potassium ions in the intermembrane space of the mitochondria was

estimated at between 175 and 207 mM (36), which is indeed significantly higher than in the cytosol, where it is typically about 140 mM (37). Among the membranes, the ones with the lowest dielectric permittivity are pure lipid bilayers, and hence for $\epsilon_{1m} < \epsilon_{2m}$, the membrane of the organelle under consideration would generally have to contain a smaller fraction of proteins than the cell plasma membrane. This is, however, markedly not the case for the inner mitochondrial membrane, where proteins represent about 76% of the mass — a higher fraction than in any other membrane (37).

The parametric studies also show that $|\Delta\Psi_{org}| / |\Delta\Psi_{cell}|$ can exceed 1 if d_1 is significantly larger than its default value of 5 nm. More generally, a sufficient condition is that the organelle membrane should be thicker than the cell membrane, $d_1 > d_2$. This is realistic for some organelles, such as the nucleus and the mitochondria, as they have a double membrane, and in mitochondria the two membranes are moreover separated by several nanometers of intermembrane space (1). Still, with a thicker membrane, a proportionally larger voltage is required for the same electric field within the membrane. As a consequence, if the electric field in the membrane is the decisive factor in electroporation, with $d_1 > d_2$ the condition $|\Delta\Psi_{org}| / |\Delta\Psi_{cell}| > 1$ is not sufficient for the organelle membrane to be electroporated, but instead roughly $|\Delta\Psi_{org}| / |\Delta\Psi_{cell}| > d_1 / d_2$ would be required.

Finally, a region with $|\Delta\Psi_{org}| > |\Delta\Psi_{cell}|$ is also reached in the parametric studies of ϵ_{1i} and ϵ_{2i} , namely at sufficiently high frequencies provided that $\epsilon_{1i} > \epsilon_{2i}$. However, as the organelle interior and the cytosol are both aqueous solutions, it is reasonable to assume that ϵ_{1i} and ϵ_{2i} are very similar. The choice of variation ranges for these two parameters primarily reflects the dependence of dielectric permittivities on the temperature, but since the cell is too small to contain significant temperature differences, change of the temperature by cooling or heating the cell suspension or a tissue will have nearly the same effect on the two permittivities.

Further analysis reveals that if the cell and organelle membranes are identical in their electric properties and their thickness, and if the cytosol is electrically identical to the organelle interior, then $|\Delta\Psi_{org}| < |\Delta\Psi_{cell}|$ at any field frequency. It should perhaps be stressed here that for such parameter values, the faster charging of the organelle membrane can not cause $\Delta\Psi_{org}$ to exceed $\Delta\Psi_{cell}$, even if the shielding of the organelle by the cell membrane is disregarded. Namely, without shielding, the rate of voltage inducement on a spherical object is inversely proportional to its radius, but the voltage plateau is directly proportional to the radius, so that on a larger object the induced voltage is necessarily larger at all times.^{***} As a consequence, the voltage induced on the cell membrane is always larger than its counterpart on the organelle membrane. At low field frequencies the shielding intensifies this effect, as the voltage on the organelle membrane starts decreasing even during the exposure (Fig. 5 illustrates this for an exposure to a direct field).

However, as Figure 3 shows, if some parameters are shifted from their default values, the outcome can change significantly. As an illustration, in Figure 4 we assume that $\sigma_{1i} = 0.5$ S/m, $\epsilon_{1m} = 3.0 \times 10^{-11}$ As/Vm, and $d_1 = 10$ nm, while keeping the other nine parameters at their default values. This study shows that on a cell characterized by the chosen parameter values, with an exposure to an alternating field with a frequency in the range of tens and hundreds of MHz, the induced voltage on the organelle could exceed its counterpart on the cell membrane by a factor of more than 3. Obviously, this is only relevant provided that σ_{1i} can actually differ that much with respect to σ_{2i} , and similarly for ϵ_{1m} with respect to ϵ_{2m} . We discuss the plausibility of this at the end of the paper, whereas we now turn to the voltages induced by a trapezoidal pulse.

^{***} This follows from the fact that for $K > 1$ and $t > 0$, we have $1 - \exp(-t/\tau) < K(1 - \exp(-t/(K\tau)))$. Namely, the two functions are equal at $t = 0$, and for their respective derivatives at $t > 0$ we have $\exp(-t/\tau)/\tau < \exp(-t/(K\tau))/\tau$.

Figure 4

3.2 Voltages induced by a trapezoidal pulse

Before focusing on specific nsPEF, it is instructive to consider the general characteristics of the voltage inducement on a nanosecond time scale. For this, we treat an onset of a direct electric field, and to keep $E(t)$ continuous, we assume that this onset is trapezoidal with a risetime T . Such a time course of the field can be described as a sum of two ramp functions, the first one with a positive slope and starting at the time 0, and the second one with the negative slope of the same size and starting at the time T ,

$$E(t) = E_0 \left[\frac{t}{T} u(t) - \frac{t-T}{T} u(t-T) \right] \quad (6)$$

where E_0 is the amplitude of the field that is reached at the end of the risetime. In the complex-frequency space, this becomes

$$E(s) = E_0 \frac{1 - e^{-sT}}{s^2 T} \quad (7)$$

In analogy with the FD study shown in Figure 2, we assume that the field amplitude is $E_0 = 5 \times 10^4$ V/m, and treat the situation at $\theta = 0$. In addition, we take $T = 1$ ns, which is on the order of magnitude of the shortest risetimes achievable with nsPEF generators. Proceeding as described in Section 2.3, we insert $E(s)$ into the expressions for $\Delta\Psi_{\text{cell}}$ and $\Delta\Psi_{\text{org}}$, write all the admittivity operators as $\Lambda = \sigma + \epsilon s$, assign all the parameters their default values, and apply the inverse Laplace transform to obtain the time courses of the two induced voltages for such an onset of the field. Shown in the top panel of Figure 5, these time courses reveal that the inducement on the cell plasma membrane is a monotonic process, while the inducement on an organelle membrane is transient; with the onset of the field, $\Delta\Psi_{\text{org}}$ increases for several hundred nanoseconds, and then recedes back to zero even if the external field persists. This is consistent with the simpler, widely used steady-state consideration of a DC exposure, where the voltage induced on the plasma membrane is given by the static Schwan equation, $\Delta\Psi_{\text{cell}} \approx 1.5 E R \cos \theta$, while everywhere in the cell interior the electric potential is practically constant.

The time courses of the two induced voltages also show that with default parameter values, $\Delta\Psi_{\text{org}}$ remains below $\Delta\Psi_{\text{cell}}$ at all times, as could be expected from the results obtained in the FD (see Fig. 2). However, if in analogy to the second FD study we set $\sigma_{\text{li}} = 0.5$ S/m, $\epsilon_{\text{lm}} = 3.0 \times 10^{-11}$ As/Vm, $d_{\text{l}} = 10$ nm, and keep the other nine parameters at their default values, the situation changes quite radically. As shown in the bottom panel of Figure 5, $\Delta\Psi_{\text{org}}$ now exceeds $\Delta\Psi_{\text{cell}}$ considerably during the first tens of nanoseconds. The general properties of the two voltages — a monotonic increase of $\Delta\Psi_{\text{cell}}$ and a transient increase of $\Delta\Psi_{\text{org}}$ followed by a decrease to zero — are unchanged.

The FD analysis (see Section 3.1) reveals that $\Delta\Psi_{\text{org}}$ can only exceed $\Delta\Psi_{\text{cell}}$ if either the cell membrane differs from the organelle membrane, or the cytosol differs from the organelle interior. From the results shown in Figure 5 it transpires that moreover, this can only occur during the first hundreds of nanoseconds after the onset of the pulse. Thus only pulse durations shorter than this can allow for selective targeting of intracellular structures, while with longer pulses the cell plasma membrane is always affected to a larger extent.

Further time courses of voltages induced by trapezoidal nsPEFs can be found in (35b).

Figure 5

3.3 Resting voltage on organelle membranes

It was already mentioned in Section 1 that the resting voltage normally present on the mitochondrial membrane is considerably larger than its counterpart on the cell plasma membrane. On each membrane, the voltage induced by an external electric field superimposes to the resting voltage, due to which the total voltage can be higher on a mitochondrial membrane than on the cell plasma membrane even with $\Delta\Psi_{\text{org}}$ equal to, or slightly below $\Delta\Psi_{\text{cell}}$. As the membrane voltages required for electroporation by nsPEF appear to be in the range of volts (28, 29), it is disputable whether a high resting voltage on an organelle membrane can alone be decisive in making this organelle the primary target of the field. Still, it could be among the reasons why mitochondria are the primary target of many observed effects of the nsPEF. This possibility has been discussed previously by Weaver (56).

3.4 Curvature of organelle membranes

Some theoretical studies suggest that the threshold value of membrane voltage required for electroporation can decrease if the membrane curvature is sufficiently high (54, 41). As the organelles are significantly smaller than the cell, the typical curvatures found in organelle membranes are generally also higher than those in the cell membrane. Due to this, it is conceivable that even with $\Delta\Psi_{\text{org}}$ somewhat lower than $\Delta\Psi_{\text{cell}}$, electroporation could affect an organelle membrane, but leave the cell membrane intact.

3.5 Voltage-gated channels in organelle membranes

This paper is mainly concerned with the conditions that would allow for electroporation of the organelle membranes, but for completeness it should be noted that some effects caused by nsPEF could also be explained without involving electroporation. Weaver (56) proposed that the membrane voltage induced on the inner mitochondrial membrane could open the mitochondrial permeability transition pore complex (MPTP). As this molecule is voltage sensitive (45, 44) and involved in the induction of apoptosis (20), apoptosis could in this manner be induced also without electroporation of the mitochondrial membranes.

4. CONCLUSIONS

In Sections 3.1 and 3.2, we investigated the circumstances under which the voltage induced by the external field on an organelle membrane can exceed its counterpart on the cell plasma membrane. The results imply that this can not occur if the electric properties of the organelle interior are very similar to those of the cytosol, and if the organelle membrane is very similar to cell membrane. On an organelle membrane considerably thicker than the cell membrane, as in mitochondria, the induced voltage can be higher even under these circumstances, but the electric field in the organelle membrane will remain below the electric field in the cell membrane, making electroporation of the former but not the latter unlikely.

However, if the organelle interior is more electrically conductive than the cytosol, or if the organelle membrane has a detectably lower dielectric permittivity than the cell membrane, the situation changes. For exposures to sinusoidal fields in the MHz range, and for the first tens of nanoseconds of exposures to pulsed fields, the voltage induced on the organelle membrane can easily exceed its counterpart on the cell membrane, as illustrated in Figure 4 and in bottom panels of Figures 5 and 6. These findings are of course only relevant provided that the assumed differences between the organelle interior and the cytosol, or between the cell and organelle membranes are realistic. Higher ionic concentrations in the interior of some organelles could result in higher conductivity of this region with respect to the cytosol, which appears to be a realistic assumption at least in the case of potassium ions in the mitochondria. Experimental estimates obtained by dielectric spectroscopy for the mitochondria (4) and the nucleus (5, 12) also corroborate that the differences between the electric conductivities of the organelle interiors and the cytosol can be considerable, and suggest that organelle membranes can also differ significantly from the cell plasma membrane in their dielectric permittivities.

Finally, as discussed in Sections 3.3, 3.4, and 3.5, there are at least three additional factors that could lead to an organelle membrane being electroporated but the cell membrane left intact: high resting voltage on the organelle membrane, high curvature of the organelle, and voltage sensitivity of certain proteins in the organelle membrane. The first and the third of these factors could also contribute to the explanation why particularly mitochondria often appear to be the primary targets of nsPEF.

TREATMENT PLANNING OF RADIOFREQUENCY ABLATION

T. SAMARAS

ARISTOTLE UNIVERSITY OF THESSALONIKI
RADIOCOMMUNICATIONS LABORATORY, DEPT. OF PHYSICS,
GR-54124 THESSALONIKI, GREECE

ABSTRACT

The treatment of cancer with the use of radiofrequency ablation under imaging guidance has attracted a lot of attention among oncologists in the recent years, as it is a minimally invasive technique of rare complications to the patients. In this work we present the results of treatment planning for the case of liver cancer treated with one electrode operating at 450kHz. We use the finite element method (FEM), implemented in a commercially available software package, to solve the combined electromagnetic and thermal problems. We explore the effect of voltage excitation, as well as of the temperature-dependent conductivity, on the resulting maximum temperature in the tissue. The influence of the blood perfusion term is also taken into consideration in our analysis. The results show that several parameters play a role in the production of a realistic treatment planning and in the investigation of the efficiency of this oncotherapeutic modality, but with the use of the necessary computer resources it is possible to study most of its aspects.

I. INTRODUCTION

The removal of tumor ('tumor ablation') is the destruction of cancerous tissue in an effort to cure the disease. It is clinically applied mainly to non-resectable tumors with the use of either thermal or chemical methods (e.g. ethanol). The thermal methods include the cooling of tissue to temperatures below -40°C (cryoablation) or its heating to temperatures higher than 50°C (thermoablation). The latter is achieved with electromagnetic radiation (RF or microwave), ultrasound and laser. More details on the techniques and the physical principles of tissue ablation can be found in [1].

Apart from liver tumors, where it is considered an established treatment modality, thermoablation is finding an increasing application in other sites like kidney, lung and bone. Most commercially available devices operate with the radiofrequency (RF) current which flows between an electrode (inserted into the tumor under the guidance of medical imaging) and a dispersive electrode (grounding pad), which is placed distally on the body surface of the patient and serves as the return path for the current. The heating of the tissues is larger where the current density is higher, i.e. next to the electrode in the tumor. The temperature can exceed 100°C , although cell death due to coagulative necrosis occurs already above 50°C . However, high tissue temperature may result in tissue carbonization (charring), which is an unwanted situation, not only because it is an irreversible effect, but mainly because it leads to an electrically insulating area which prevents the current from flowing.

There are currently several limitations in tumor thermoablation. Imaging techniques should be improved to allow better guidance of the electrode inside the tumor and evaluation of the thermal lesion. New techniques must be employed (e.g. multiple electrode systems) in order to increase the coagulative zones, instead of inserting a single electrode more than once in the tumor. Finally, the treatment efficiency is compromised next to large blood vessels, which advect a large portion of the heat developed in the target area, leading to lower than expected temperatures [2]. Such shortcomings make the introduction of treatment planning an important factor in securing quality assurance of the treatment and maximizing its outcome.

In this work we will present some of the numerical aspects and problems in the treatment planning of RF ablation with a single electrode inserted inside the liver.

II. METHODOLOGY

Formulation

At first look treatment planning of RF ablation appears like a two-step procedure. In the frequency range of 450–550 kHz, where most probes operate, the wavelength of the electromagnetic field inside the tissue is several orders of magnitude larger than the size of the ablation electrodes, i.e. we deal with a quasi-static problem. At these frequencies conduction current is more important in living tissues (due to electrolyte ions present in them) than displacement current. Therefore, in order to solve the electrical problem it is necessary to use Laplace's equation,

$$\nabla(\sigma \nabla V) = 0 \quad (1)$$

where σ is tissue conductivity (S/m) and V is the electric potential (V). It is assumed that no current sources at the same frequency like the externally imposed current are present inside the human body. Having calculated the electric field, the power per unit mass (W/kg) dissipated in the tissues, i.e. the Specific Absorption Rate (SAR), evaluates to

$$SAR = \frac{\sigma}{\rho} |E|^2 = \frac{1}{\sigma \rho} |J|^2 \quad (2)$$

where ρ is the mass density (kg/m³) and J the current density (A/m²). This term can be used as an input to the Bioheat Transfer Equation (BHTE) of Pennes' [3]

$$\rho c \frac{dT}{dt} = \nabla \cdot (k \nabla T) - \rho_b c_b \omega_b (T - T_b) + Q_m + Q_{RF} \quad (3)$$

where k is the thermal conductivity (W/(m K)), c is the specific heat (J/(kg K)), ω_b is the blood perfusion rate (in m³ of blood per m³ and per s), Q_m is the metabolic heat generation rate (W/m³) and Q_{RF} is the volumetric heat generation rate (W/m³) due to the RF current:

$$Q_{RF} = \rho SAR \quad (4)$$

The subscript b denotes 'blood'.

However, equations (1) and (3) are coupled, because electrical conductivity σ changes with temperature, i.e. the problem is non-linear and this can affect the final temperature calculated with numerical techniques [4],[5].

Numerical model

The coupled differential equations were solved numerically with the commercially available software package FEMLAB 3.1i (COMSOL AB, Stockholm, Sweden), which implements the Finite Element Technique (FEM). The assumed electrode (probe) is shown in Figure 1. The probe had a diameter of 0.3cm and consisted of two parts. The lower tip of 2cm in length was set at a constant voltage V_0 , whereas the upper part of 4cm in length was supposed to be insulated electrically. The whole probe was assumed thermally insulated, which is not far from reality for electrodes inserted in catheters.

Figure 1. The electrode (probe) assumed in the numerical simulations

The probe was inserted inside a cubical volume of liver tissue with edge dimension of 12cm (Figure 2). The properties of the tissue and blood are given in Table 1. At the sides of the cube Dirichlet boundary conditions were set for both the electric and the thermal problem: The temperature was set at 37°C and the voltage at 0V.

Table 1. Physical properties of model

Property	Value
Electrical conductivity of liver (37°C)	0.143 S/m
Thermal conductivity of liver	0.502 W/(m K)
Specific heat of liver	3600 J/(kg K)
Mass density of liver	1060 kg/m ³
Specific heat of blood	4180 J/(kg K)
Mass density of blood	1000 kg/m ³
Blood perfusion rate	0.0064 1/s
Blood temperature	37°C

The variation of electrical conductivity with temperature was adopted from [4] and can be summarized in

$$\sigma(T) = 0.1151 - [0.00226 \times (25 - T)] + [0.00000925 \times (25 - T)^2] \quad (5)$$

where T is the tissue temperature in °C. The conductivity and the temperature were sampled every 10 or 30s during the whole simulation of a treatment lasting 15min.

Figure 2. FEM model used for solving the problem

IV. RESULTS

In order to show the differences between the linear and the non-linear problem, the equations were solved both for constant electrical conductivity of liver and for temperature dependent according to equation (5). The shape of the distribution of the electric potential inside the computational domain does not change very much in the two cases (Figure 3), nor does the distribution of the final temperature (Figure 4).

However, the maximum temperature (calculated at the tip of the probe) is different in the two cases for the same voltage V_0 applied. Figure 5 shows that when the conductivity does not vary with temperature the maximum temperature is underestimated; this is especially true for higher probe voltages V_0 . It is also clear from Figure 5 that the maximum temperature does not depend linearly on V_0 .

Figure 3. Distribution of electric potential in the tissue for (a) constant and (b) temperature dependent electrical conductivity

Figure 4. Final (after 15min) temperature distribution in the tissue for (a) constant and (b) temperature dependent electrical conductivity

Figure 5. Time course of the temperature at the probe's tip for constant (dashed lines) and temperature dependent (solid lines) electrical conductivity at various source voltages

TRANSMIT POWER CONTROL IN MOBILE COMMUNICATIONS AND ITS POTENTIAL FOR A REDUCTION OF EMF EXPOSURE

**MICHAEL A. BALDAUF, SANDRA KNÖRZER,
THORSTEN KAYSER, AND WERNER WIESBECK**

***INSTITUT FÜR HÖCHSTFREQUENZTECHNIK UND ELEKTRONIK,
UNIVERSITÄT KARLSRUHE (TH), KAISERSTR. 12, 76131 KARLSRUHE, GERMANY***

Abstract

The application of transmit power control in mobile communications allows a decrease of the maximum output power to a lower level per link. Technical reasons to utilize transmit power control are the reduction of co-channel interference and an increase in the battery lifetime of the mobile terminal. Considering the well known COST-Hata wave propagation model the steady state transmit powers for base and mobile stations in typical scenarios are calculated. It is shown that for GSM base stations the optional transmit power control has only a small impact onto the human exposure to electromagnetic fields. In contrast to this the transmit power of a GSM mobile phone can be lowered clearly compared to the maximum output power, when applying transmit power control. For UMTS mobile phones there is even a higher potential for an exposure reduction.

Introduction

In mobile radio networks there are basically two sources of electromagnetic fields (EMF). On the one hand there is a fixed base station which transmits a signal with a constant level at all times to allow the mobile station to identify it. The more users there are in a cell the more transmit power is needed to serve the customers with user specific information. On the other hand, there is a mobile station which transmits generally only when the user actively uses the mobile phone e.g. by having a voice connection.

For the far field exposure due to base stations the exposure can be conveniently described by the electric field strength (E) or the power density (S). For the human head held close to a mobile phone there is a strongly varying near field over different tissue types. Therefore, a determination of the specific absorption rate (SAR) is necessary. The exposures which encounter in real life due to base and mobile stations are very different compared to the limit values. Safety distances to base stations based on the ICNIRP Guidelines [1] are typically just a few meters [2]. Thus, the exposures due to base stations are usually well below the limits. However, concerning the exposure to mobile phones some phones are quite close to the SAR limit [3]. In conformance tests the mobile phone transmits with its maximum transmit power to simulate worst case conditions [4].

The possibility of transmit power control (TPC) allows a reduction of the transmit power. Hence, TPC is a means to reduce interference in mobile cellular networks. Additionally there is a remarkable increase in battery lifetime for mobile terminals. In 3rd generation's UMTS networks TPC at the mobile terminal is a must in order to allow a reception of all users with the wanted signal to noise plus interference ratio (SNIR) at the base station. This paper deals with the potential of the exposure reduction of TPC.

Network layout

In the simulations a simplified hexagonal network layout with three sector antennas in each hexagon is considered. Base stations are placed at the centers of the hexagons (cf. Fig. 1). There are two rings of hexagons surrounding a center hexagon to take the exposure of surrounding cells into account. The technical configuration is the same for all base stations. The exposure is evaluated for the center hexagon. Therefore, this hexagon is overlayed with a regular grid of about 100 000 equidistant points.

Fig. 1: Left: Hexagonal cell showing the orientation of the sector antennas (arrows). Right: Convention for angles in a spherical coordinate system.

Fig. 2: Exposure scenario.

Exposure Scenario

Fig. 2 shows the considered exposure scenario in a side view. All base stations (BS) are mounted at a height h_{BS} , the mobile stations (MS) are at a height $h_{MS} = 1.5$ m. The horizontal separation of the MS to the BS is given by the distance R . The variable R_C denotes the cell radius, which is defined in Fig. 1. In the simulations cell radii of $R_C = 1$ km and $R_C = 6.3$ km are regarded. Since for smaller cell sizes the antennas are typically mounted at a lower height the antenna heights h_{BS} of the BS are chosen to be dependent on the cell radius R_C . For the smaller cell radius ($R_C = 1$ km) the antenna height $h_{BS} = 12.6$ m for the larger cell radius ($R_C = 6.3$ km) $h_{BS} = 41$ m.

At the BS there are three Kathrein 742212 antennas [5] mounted with $\psi = \{90^\circ, 210^\circ, 330^\circ\}$ to cover three sectors (cf. Fig. 1). The pattern of the antenna with a gain $G_{BS} = 18$ dBi is shown in Fig. 3. For the simulation the pattern is smoothed and limited to take an increased field strength due to multipath propagation into account. To concentrate more energy on the ground a declination of the antenna pattern can be done electrically. The considered sector antennas are tilted down slightly. The downtilt angle is chosen in such a manner that the direction where the antenna has its half power beamwidth above the main beam direction is directed at the height of a MS's antenna at the cell radius R_C .

Fig. 3: Elevation pattern of Kathrein's 742212 with 3° electrical downtilt. Shown is the pattern $C_{BS}(\theta)$ for one polarization of the X-polarized antenna. Dark line: unmodified manufacturer data; light line: smoothed and limited pattern data.

Emission versus Exposure

A measure of the biological relevance of electromagnetic fields is the exposure. Transmitters are often classified by their transmit power (emission). In situations where there is no change in the loss between transmitter and the

human body the change in transmit power is directly proportional to the change in exposure. An example is a mobile station held close to the head. As long as the terminal is not moved the exposure is proportional to the transmit power. However, moving e.g. the mobile terminal further away from the head will typically lead to a lower absorption loss of the head. As a result of this, the transmit power can be lowered. Furthermore, the distance to the head is increased. Both facts will lead in sum to an exposure that is lower compared to the situation where the mobile phone is closer to the human head. However, the change in exposure is no longer directly proportional to the change in emission.

Considering two cell radii R_C with different BS antenna heights h_{BS} yields different path losses in the scenarios. Since the exposure is in the far field it can be expressed as power density S . Comparing the power density S allows a direct comparison of the exposure. In contrast to this, for the human exposure due to the mobile phone a constant position of the phone to the head will be assumed. Therefore, the change in exposure is then directly proportional to the change in transmit power.

Path loss model

In order to derive the exposure a knowledge of the path loss L between all sources of EMF and the points that are defined for an evaluation is necessary. The path loss model chosen for the simulations is the well known COST-Hata model [6]. The model takes a correction term for open areas into account [7]. For this reason, the building development can be described by a parameter b . This parameter ranges from $b = 0 \dots 1$, $b = 0$ corresponds to an open area whereas $b = 1$ corresponds to an urban area. For more information about the parameter b see [8]. The uplink and downlink frequencies are chosen to be $f = 2$ GHz. A deviation between uplink and downlink frequency is not considered since the frequency difference is usually small in prevalent frequency division duplex (FDD) systems, and therefore has only a negligible influence on the path loss. The isotropic path loss L_i according to the COST-Hata model is given by:

$$\frac{L_i}{\text{dB}} = 158.16 - 13.82 \log \left(\frac{h_{BS}}{\text{m}} \right) + \left(44.9 - 6.55 \log \left(\frac{h_{BS}}{\text{m}} \right) \right) \log \left(\frac{R}{\text{km}} \right) + 32.52 b \quad (1)$$

where use of the fixed MS antenna height and frequency has been made. Formula (1) gives the path loss for isotropic antennas, therefore the name isotropic path loss L_i . Using directional antennas will change the path loss to:

$$\frac{L}{\text{dB}} = \frac{L_i}{\text{dB}} + \frac{G_{BS} C_{BS}^2(\theta_{BS}, \psi_{BS})}{\text{dB}} + \frac{G_{MS} C_{MS}^2(\theta_{MS}, \psi_{MS})}{\text{dB}} \quad (2)$$

Herein G_{BS} and G_{MS} are the gains of the base and mobile stations, respectively. The gains have to be weighted by the square of the antenna patterns C^2 . Since the patterns depend on the viewing angle different indices for the angles θ and ψ are used for the base and mobile station. Depending on the gains G and patterns C the path loss L can be larger or smaller than the isotropic path loss L_i . Typically the base station antennas are directed in order to radiate much energy into directions where the isotropic path loss L_i is large. For the antenna of the mobile station an isotropic radiator is assumed, therefore, the last term in (2) vanishes for the calculation of the path loss L .

For distances close to the base station (1) might yield path losses which are smaller than for a free space propagation (unobstructed line of sight). If this happens the path loss in the model is replaced by the value of the path loss for free space condition.

Path Loss in a Cell

Four cell types were considered for an evaluation of the path loss L in a cell. These are:

- a large urban cell
- a small urban cell
- a large rural cell
- a small rural cell

The term “large” refers to a cell size of $R_C = 6.3$ km, whereas the term “small” refers to a cell size of $R_C = 1$ km. For the urban cell the parameter b in (1) is chosen to be $b = 0.8$ for the rural cell $b = 0.2$. Figs. 4-7 show the distribution of the path losses in the four types of regions for different antenna types. Fig. 4 shows the probability density function (PDF) of the path loss according to (1) with $b = 0.2$. Figs. 5-7 include a log-normal fading with a standard deviation $\sigma = 7$ dB. The left hand sides (LHS) of the figures show the PDF for the larger cell sizes whereas the right hand sides (RHS) show the PDF for the smaller cell sizes. Whereas Figs. 4 and 5 refer to an isotropic antenna at the BS the Figs. 6 and 7 regard the Kathrein 742212 as BS antenna. Comparing

Figs. 4 and 5 shows that considering a log-normal fading shows broader distribution of the PDF. The installation of sector antennas with a high gain will allow a significant reduction of the path loss (compare Figs. 5 and 6). Increasing the building development would yield higher path losses (cf. Fig. 7).

Fig. 4: PDF of the isotropic path loss in a rural region. Parameters: $b = 0.2$. LHS: $R_C = 6.3$ km, RHS: $R_C = 1$ km. No log-normal fading.

Fig. 5: PDF of the isotropic path loss in a rural region. Parameters: $b = 0.2$. LHS: $R_C = 6.3$ km, RHS: $R_C = 1$ km. Log-normal fading ($\sigma = 7$ dB).

Fig. 6: PDF of the path loss for the considered directional antenna in a rural region. Parameters: $b = 0.2$. LHS: $R_C = 6.3$ km, RHS: $R_C = 1$ km. Log-normal fading ($\sigma = 7$ dB).

Fig. 7: PDF of the path loss for the considered directional antenna in an urban region. Parameters: $b = 0.8$. LHS: $R_C = 6.3$ km, RHS: $R_C = 1$ km. Log-normal fading ($\sigma = 7$ dB).

Link budget

To decode a signal correctly a minimum required signal quality must be reached. This quality can be given in general as a SNIR (signal-to-noise-plus-interference-ratio). The noise is thermal noise and can't be reduced below a certain value which is dependent on the system temperature and bandwidth. For CDMA systems (e.g. UMTS) where a lot of users share the same frequency at the same time interference has to be taken into account. Interference can be interpreted as noise and vice versa.

GSM systems use frequency division multiple access (FDMA) and time division multiple access (TDMA) to separate users. Assuming sufficient carriers are available the effect of interference needs not to be considered. To determine the required transmit powers at the base and mobile stations it is sufficient to regard the necessary received power P_R per user at the receiving end in combination with the path loss. P_R is independent of the network load and given by the transmit power P_T minus the path loss L between the transmitter and the receiver. Knowing the path loss the minimum required P_T can be determined.

For the determination of the maximum path loss L and therefore also for the mandatory channel no log-normal fading is considered. The transmit power of the base and mobile stations are increased by 20 dB to account for additional propagation losses as the absorption of energy in the human body and effects of small-scale fading. For simplicity fading is not explicitly considered in the determination of the transmit powers. For the mobile stations fading is considered in a later step.

The transmit power of the BS is labeled by $P_{T,BS}$ and the transmit power of the MS by $P_{T,MS}$.

TPC at the BS

If there is no TPC implemented the PDF of the received signal has the same shape as the path loss. Power control can be used only for dedicated channels which don't have to be received at all MS.

The channel configuration of the considered GSM system is shown in Fig. 8. Shown are two carriers which are allocated to different frequencies around $f = 2$ GHz. On the LHS there is the BCCH carrier. Each of the eight bins corresponds to one time slot. Via this carrier information about the cell is transmitted in one slot. The seven other time slots on this carrier are reserved for additional signaling purposes or e.g. SMS services. If the information of these slots is not needed they are filled up with dummy bits and transmitted with full power. This carrier can't be power controlled. Active users having a voice connection are put on another carrier on which power control is available. The transmit power in a power controlled slot is decreased by ΔPC compared to the power of the BCCH carrier. The maximum power reduction which is possible is given by ΔPC_{max} . The simulations were done assuming a varying range of the parameter ΔPC_{max} .

Fig. 8: Channel configuration of the considered GSM system.

In the following three different numbers of carriers N are investigated. The numbers chosen are $N = 1, 4$ and 6 . In the case of $N = 1$ only the BCCH carrier is transmitting. $N = 4$ and 6 correspond to typical channel configurations. The required user densities n for these three cases are:

- $n = 0$ ($N = 1$)
- $n = 0.70 / \text{km}^2$ ($R_C = 6.3$ km, $N = 4$)
- $n = 1.16 / \text{km}^2$ ($R_C = 6.3$ km, $N = 6$)
- $n = 27.71 / \text{km}^2$ ($R_C = 1$ km, $N = 4$)
- $n = 46.18 / \text{km}^2$ ($R_C = 1$ km, $N = 6$)

Whereas in the large cell ($R_C = 6.3$ km) the considered number of carriers can be filled with small user densities much higher user densities are needed for the smaller cell size ($R_C = 1$ km).

Figs. 9-14 show the transmit power $P_{T,BS}$ per sector and the average power density S_{avg} versus the maximum possible power reduction ΔPC_{max} , respectively, for three cases. There are no results given for the case of the large urban cell. For this case the path loss would be too high for a lot of mobile stations to reach the base stations.

If there is only the mandatory BCCH carrier on air TPC would yield no power reduction since this carrier can't be power controlled ($N = 1$ in the figures). If there are active users in time slots which can be power controlled the total transmit power fed into the sector antenna can be lowered typically by just 3 to 4 dB. A higher value of ΔPC_{max} allows lower transmit powers. Choosing ΔPC_{max} larger than 10 dB shows no further positive effect in terms of transmit power reduction.

The more channels that are in use, the higher is the reduction of the transmit power when using TPC. The increase from 4 carriers to 6 carriers shows no significant effect. A change in transmit power within one configuration is directly proportional to the change in exposure (compare the figures in one row).

Furthermore, the results show that there is no one-to-one equivalence of emission (transmit power) and exposure

(power density). In the case of the rural cell the transmit power of the BS $P_{T,BS}$ in the large cell (cf. Fig. 9) is much higher than in the smaller cell (cf. Fig. 11). However, the exposures in both network configurations are almost the same (compare Figs. 10 and 12). In the small urban cell the transmit power is much higher than in the small rural cell but the exposure is higher by just a small amount. This is due to the fact that in the urban network not only the transmit power is higher but also the path loss is much higher than in the rural case.

Fig. 9: Transmit power per sector versus the maximum power reduction. Parameters: $R_C = 6.3$ km, $b = 0.2$ (rural area).

Fig. 10: Average power density versus the maximum power reduction. Parameters: $R_C = 6.3$ km, $b = 0.2$ (rural area).

Fig. 11: Transmit power per sector versus the maximum power reduction. Parameters: $R_C = 1$ km, $b = 0.2$ (rural area).

Fig. 12: Average power density versus the maximum power reduction. Parameters: $R_C = 1$ km, $b = 0.2$ (rural area).

Fig. 13: Transmit power per sector versus the maximum power reduction. Parameters: $R_C = 1$ km, $b = 0.8$ (urban area).

Fig. 14: Average power density versus the maximum power reduction. Parameters: $R_C = 1$ km, $b = 0.8$ (urban area).

For UMTS there are also some channels which are transmitted at all times with a constant level. As in GSM, user specific channels can be also power controlled. Simulations have shown that the results for UMTS are very similar to those shown for GSM.

TPC at the MS

The mobile station can adjust its transmit power in a given range. For GSM 1800 mobile phones the transmit power $P_{T,MS}$ can be adjusted according to the specifications from 0 dBm to 30 dBm [9]. Fig. 15 shows the transmit power of the mobile station when there is no restriction on power control. In the large cell there are some MSs which would transmit with a very high transmit power (LHS of Fig. 15). In practice the maximum TPC is restricted to 30 dBm [9] (LHS of Fig. 16). Since 20 dB are added to the transmit powers as a safety margin there might be a quality decrease for MSs demanding a higher transmit power than possible. MSs that would need more than 50 dBm of transmit power definitely can't be served due to their restriction of the maximum output power of 30 dBm. However, this is only a relatively small part. Comparing large and small cell sizes shows that the transmit power in the smaller cell can be lowered by about 20 dB. Furthermore, comparing the Figs. 15 and 16 it is clear that the implemented lowest transmit power for MSs in GSM networks is not exposure optimized since a lot of MSs would be able to lower their transmit power below $P_{T,MS} = 0$ dBm in small cells.

Fig. 15: PDF of the mobile station's transmit power in a rural GSM network. The transmit power can reach arbitrary values. Parameters: $b = 0.2$; LHS: $R_C = 6.3$ km, RHS: $R_C = 1$ km.

Fig. 16: PDF of the mobile station's transmit power in a rural GSM network. The transmit power can be in the range of the specified TPC. Parameters: $b = 0.2$; LHS: $R_C = 6.3$ km, RHS: $R_C = 1$ km.

For UMTS mobile phones the maximum output power typically used for voice transmissions is $P_{T,MS} = +21$ dBm. Since every transmitting mobile station produces interference an optimum received power at the base station is a must. The specifications [10] demand a minimum transmit power of $P_{T,MS} = -50$ dBm or lower. Fig. 17 shows the chosen transmit power of the MS $P_{T,MS}$ if there is no restriction of the TPC. Setting a lower limit of $P_{T,MS} = -50$ dBm shows that a very small part of the mobile stations in the small cell is then transmitting with a higher power than necessary (cf. Fig. 18). Since a transmit power that is too high would cause interference at the BS this situation should be avoided. Therefore, the range of the TPC in UMTS should be extended even further.

Fig. 17: PDF of the mobile station's transmit power in a rural UMTS network. The transmit power can reach arbitrary values. Parameters: $b = 0.2$; Channel model: Veh. A, MS speed = 3 km/h. LHS: $R_C = 6.3$ km, RHS: $R_C = 1$ km.

Fig. 18: PDF of the mobile station's transmit power in a rural UMTS network. The transmit power can be lowered only to -50 dBm. Parameters: $b = 0.2$; Channel model: Veh. A, MS speed = 3 km/h. LHS: $R_C = 6.3$ km, RHS: $R_C = 1$ km.

Comparing the results for GSM and UMTS suggests that UMTS MSs need much lower transmit powers than GSM MSs. The reason for this is that typical configurations of the MSs are assumed. Since interference due to the reception of multiple MSs at the same frequency and time is not a dominant problem at GSM BSs, network operators tend to choose transmit powers at the MS which are clearly higher than those needed at a certain instant of time. This is due to fact that the implemented power control can only react very slowly on changing propagation conditions. In contrast to this interference in UMTS networks at the BS is really a problem. Therefore, network operators have to choose the MS's transmit power as low as possible. Fast TPC at the MS helps to adjust the transmit power every 1/1500 seconds. For this reason there is no need for adding a large security factor to account for fading effects as long as the MS is moving with a low speed.

Conclusion

Interference reduction and an increase in battery lifetime are technical reasons to implement transmit power control. The reduction of the human exposure to electromagnetic fields is rather a side effect. It is shown that the decrease in exposure using power control at the base station is rather small since the base station has to transmit site specific information in a broadcast mode at all times. From an exposure point of view a maximum power decrease of 10 dB per power controlled link is sufficient. A larger power reduction will not help to decrease the exposure to electromagnetic fields. Taking advantage of transmit power control at the mobile station the transmit power and, therefore, the exposure due to the mobile phone can be lowered clearly by several orders of magnitude. Whereas the power control range of UMTS mobile phones corresponds in a very good manner to the path loss the power control range of GSM phones is clearly not exposure optimized.

Abstract

The electric field produced by electric power lines is usually calculated with the use of numerical methods. However, the analytical calculation of the electric field is preferable, because it leads to a mathematical expression, which shows the field's dependencies from all the line parameters.

Initially, a method to derive the analytical formulas of the intensity of the electric field produced by electric power lines, is presented in this paper. This method is based on the analysis of the intensity of the electric field into the sum of two multipole expansions and in the use of double complex numbers for the simplification of the mathematical expressions. Due to the asymmetry of conductors' charges, they are analyzed in their symmetrical components. Afterwards, accurate analytical formulas of the intensity of the electric field for simple circuit power lines with conductors in triangular arrangement are given, which are valid at any point in the vicinity of lines. Beyond the accurate formulas, simpler approximate formulas are presented, which give the electric field with known precision.

1 Introduction

During the last 25 years the electric and magnetic fields are considered more and more as environmental factors. The International Commission on Non-Ionizing Radiation Protection (ICNIRP) published in 1998 the guidelines [1]. In these guidelines, the limit values are 5kV/m and 100μT for the public exposure and 10kV/m and 500μT for the occupational exposure. The World Health Organization (WHO) and the European Union (E.U.) have adopted the limits of ICNIRP [2,3]. These limits are included in the national legislations of the most countries in the E.U.

In the present paper analytical formulas are developed for the calculation of the intensity of the electric field in the vicinity of single circuit power lines. Corresponding analytical formulas for the calculation of magnetic flux density were published in [4]. The analytical formulas provide the advantage of easy and precise calculation of the field intensities and of a simpler parametrical investigation for evaluating the effect of various parameters, without the use of numerical methods. Therefore, they are appropriate for the assessment of the public exposure, e.g. in the frames of epidemiological studies.

2 Calculation procedure

2.1 Electric field produced by power lines

Figure 1 shows the model of a simple circuit power line and a point of interest P for the calculation of the intensity of the electric field. It is considered that the line route is straight and that its length is very big in comparison with the distances between the conductors and the distances of conductors from the ground. The three conductors in figure 1 bring charges Q_1 , Q_2 and Q_3 , which are sinusoidal varying in time, while their distances from the point P are R_1 , R_2 and R_3 respectively. The intensity of electric field E_k in point P, produced by a conductor k, is given by

$$\underline{E}_k = \frac{Q_k}{2\pi\epsilon_0} \left(\frac{1}{R_k^2} \underline{R}_k' - \frac{1}{R_k^2} \underline{R}_k \right) \quad (2.1)$$

where $\epsilon_0 = \frac{1}{36\pi} 10^{-9} \frac{A \cdot s}{V \cdot m}$ is the electric permittivity of free space, \underline{R}_k the vector distance from the k conductor to the point P , \underline{R}_k' the vector distance from the image of the k conductor to point P and R_k , R_k' the modulus of vectors \underline{R}_k and \underline{R}_k' respectively.

Figure 1. Model of a single circuit power line with the conductors' images

In the general case, a line with n conductors may be considered. Using the superimposition theorem, the intensity of electric field \underline{E} , produced by the line is equal to the sum of the fields produced by each conductor separately,

$$\begin{aligned} \underline{E} &= \sum_{k=1}^n \underline{E}_k = \frac{1}{2\pi\epsilon_0} \sum_{k=1}^n Q_k \left(\frac{1}{R_k^2} \underline{R}_k' - \frac{1}{R_k^2} \underline{R}_k \right) \Rightarrow \\ \underline{E} &= \frac{1}{2\pi\epsilon_0} \sum_{k=1}^n Q_k \left(\frac{1}{\underline{R}_k'} - \frac{1}{\underline{R}_k} \right) \end{aligned} \quad (2.2)$$

Relation (2.2) is usually used for the numerical calculation of the intensity of the electric field. However, the summing operation doesn't allow this formula to be readily applied for the calculation of the electric field and makes it unsuitable for reaching general conclusions for the electric field properties and its dependencies on the various parameters of the line.

2.2 Double complex numbers and multipole expansions

The relations for the electric field vector are simplified if complex numbers are used for the representation of vector distances. On the other hand, complex numbers are used for the representation of sinusoidal varying quantities in time (phasors), such as conductors' charges, so finally double complex numbers are required. Book [5] contains the theoretical basis of double complex numbers, in [4] they are used for the calculation of magnetic flux density and in [6] to express the elliptically polarized vector of the electric field of light.

For the representation of space vectors the set of complex numbers C_1 is used, with the imaginary part j , for example $\mathbf{R}_k = x_k + jy_k$, while for the representation of sinusoidal varying quantities in time, the set C_2 with the imaginary part i is used, for example $\underline{Q}_k = Q_k e^{i\omega t}$.

Figure 1 shows that each conductor k may be characterized by the vector distance \mathbf{d}_k from the reference point O , which is a central point of the real conductors' system. The image of each conductor k may be characterized by the vector distance \mathbf{d}'_k from the reference point O' , which is a central point for the conductors' images' system. The points O and O' are close to but not necessarily the centers of the conductors' systems. Their choice is a matter of experience and is made in order to simplify the mathematical expressions.

Replacing $\mathbf{R}_k = \mathbf{R} - \mathbf{d}_k$ and $\mathbf{R}'_k = \mathbf{R}' - \mathbf{d}'_k$ in (2.2), it becomes (2.3).

$$\underline{\mathbf{E}} = \frac{1}{2\pi\epsilon_0} \sum_{k=1}^n Q_k \left(\frac{1}{\frac{\mathbf{R}'}{\mathbf{R}} - \frac{\mathbf{d}'_k}{\mathbf{R}}} - \frac{1}{\frac{\mathbf{R}}{\mathbf{R}} - \frac{\mathbf{d}_k}{\mathbf{R}}} \right) \quad (2.3)$$

Using the well-known relations (2.4) in (2.3), the intensity of the electric field results as the sum of two multipole expansions, one from the real conductors' system and the other from the conductors' images' system, relation (2.5).

$$\left(\frac{\mathbf{R}'}{\mathbf{R}} - \frac{\mathbf{d}'_k}{\mathbf{R}} \right)^{-1} = \sum_{\lambda=1}^{\infty} \frac{\mathbf{d}'_k{}^{\lambda-1}}{\frac{\mathbf{R}'}{\mathbf{R}}{}^{\lambda}} \quad (2.4a)$$

$$\left(\frac{\mathbf{R}}{\mathbf{R}} - \frac{\mathbf{d}_k}{\mathbf{R}} \right)^{-1} = \sum_{\lambda=1}^{\infty} \frac{\mathbf{d}_k{}^{\lambda-1}}{\frac{\mathbf{R}}{\mathbf{R}}{}^{\lambda}} \quad (2.4b)$$

$$\underline{\mathbf{E}} = \frac{1}{2\pi\epsilon_0} \sum_{k=1}^n Q_k \left(\sum_{\lambda=1}^{\infty} \frac{\mathbf{d}'_k{}^{\lambda-1}}{\frac{\mathbf{R}'}{\mathbf{R}}{}^{\lambda}} - \sum_{\lambda=1}^{\infty} \frac{\mathbf{d}_k{}^{\lambda-1}}{\frac{\mathbf{R}}{\mathbf{R}}{}^{\lambda}} \right) \Rightarrow$$

$$\underline{\mathbf{E}} = \sum_{\lambda=1}^{\infty} \underline{\mathbf{E}}'_{(\lambda)} + \sum_{\lambda=1}^{\infty} \underline{\mathbf{E}}_{(\lambda)} \quad (2.5)$$

The terms $\underline{\mathbf{E}}'_{\lambda}$ and $\underline{\mathbf{E}}_{\lambda}$ are called λ order terms and are given by the relations (2.6)

$$\underline{\mathbf{E}}'_{(\lambda)} = \frac{1}{2\pi\epsilon_0} \cdot \frac{\underline{\mathbf{M}}'_{\lambda}}{\frac{\mathbf{R}'}{\mathbf{R}}{}^{\lambda}} \quad (2.6a)$$

$$\underline{\mathbf{E}}_{(\lambda)} = -\frac{1}{2\pi\epsilon_0} \cdot \frac{\underline{\mathbf{M}}_{\lambda}}{\frac{\mathbf{R}}{\mathbf{R}}{}^{\lambda}} \quad (2.6b)$$

where the factors $\underline{\mathbf{M}}'_{\lambda}$ and $\underline{\mathbf{M}}_{\lambda}$ are called λ order moments for the conductors' images' system and the real

conductors' system respectively and are given by the relations (2.7).

$$\underline{\underline{\mathbf{M}}}_{\lambda} = \sum_{k=1}^n \underline{\underline{\mathbf{Q}}}_k \underline{\underline{\mathbf{d}}}_k^{\lambda-1} \quad (2.7a)$$

$$\underline{\underline{\mathbf{M}}}_{\lambda} = \sum_{k=1}^n \underline{\underline{\mathbf{Q}}}_k \underline{\underline{\mathbf{d}}}_k^{\lambda-1} \quad (2.7b)$$

The multipole expansion, which appears in relation (2.5), is a series of infinite terms, each inversely proportional to an increasing power of the distance and has been used in [4] and [7] for the calculation of magnetic field produced by electric power lines.

2.3 Analysis of charges in symmetrical components

The calculation of the conductors' charges is necessary in order to calculate the intensity of the electric field. In the case of a single circuit power line, figure 1, the conductors' charges $\underline{\underline{\mathbf{Q}}}_1$, $\underline{\underline{\mathbf{Q}}}_2$ and $\underline{\underline{\mathbf{Q}}}_3$ are given by the relations (2.8).

$$\underline{\underline{\mathbf{Q}}}_1 = \frac{\underline{\underline{\mathbf{D}}}_1}{\underline{\underline{\mathbf{D}}}} \quad , \quad \underline{\underline{\mathbf{Q}}}_2 = \frac{\underline{\underline{\mathbf{D}}}_2}{\underline{\underline{\mathbf{D}}}} \quad , \quad \underline{\underline{\mathbf{Q}}}_3 = \frac{\underline{\underline{\mathbf{D}}}_3}{\underline{\underline{\mathbf{D}}}} \quad (2.8)$$

The terms $\underline{\underline{\mathbf{D}}}_1$, $\underline{\underline{\mathbf{D}}}_2$, $\underline{\underline{\mathbf{D}}}_3$ and $\underline{\underline{\mathbf{D}}}$ are calculated by the relations (2.9)

$$\underline{\underline{\mathbf{D}}}_1 = \begin{vmatrix} \underline{\underline{\mathbf{V}}}_1 & \underline{\underline{\mathbf{S}}}_{12} & \underline{\underline{\mathbf{S}}}_{13} \\ \underline{\underline{\mathbf{V}}}_2 & \underline{\underline{\mathbf{S}}}_{22} & \underline{\underline{\mathbf{S}}}_{23} \\ \underline{\underline{\mathbf{V}}}_3 & \underline{\underline{\mathbf{S}}}_{32} & \underline{\underline{\mathbf{S}}}_{33} \end{vmatrix} \quad , \quad \underline{\underline{\mathbf{D}}}_2 = \begin{vmatrix} \underline{\underline{\mathbf{S}}}_{11} & \underline{\underline{\mathbf{V}}}_1 & \underline{\underline{\mathbf{S}}}_{13} \\ \underline{\underline{\mathbf{S}}}_{21} & \underline{\underline{\mathbf{V}}}_2 & \underline{\underline{\mathbf{S}}}_{23} \\ \underline{\underline{\mathbf{S}}}_{31} & \underline{\underline{\mathbf{V}}}_3 & \underline{\underline{\mathbf{S}}}_{33} \end{vmatrix} \quad , \quad \underline{\underline{\mathbf{D}}}_3 = \begin{vmatrix} \underline{\underline{\mathbf{S}}}_{11} & \underline{\underline{\mathbf{S}}}_{12} & \underline{\underline{\mathbf{V}}}_1 \\ \underline{\underline{\mathbf{S}}}_{21} & \underline{\underline{\mathbf{S}}}_{22} & \underline{\underline{\mathbf{V}}}_2 \\ \underline{\underline{\mathbf{S}}}_{31} & \underline{\underline{\mathbf{S}}}_{32} & \underline{\underline{\mathbf{V}}}_3 \end{vmatrix} \quad , \quad \underline{\underline{\mathbf{D}}} = \begin{vmatrix} \underline{\underline{\mathbf{S}}}_{11} & \underline{\underline{\mathbf{S}}}_{12} & \underline{\underline{\mathbf{S}}}_{13} \\ \underline{\underline{\mathbf{S}}}_{21} & \underline{\underline{\mathbf{S}}}_{22} & \underline{\underline{\mathbf{S}}}_{23} \\ \underline{\underline{\mathbf{S}}}_{31} & \underline{\underline{\mathbf{S}}}_{32} & \underline{\underline{\mathbf{S}}}_{33} \end{vmatrix} \quad (2.9)$$

where $\underline{\underline{\mathbf{V}}}_1$, $\underline{\underline{\mathbf{V}}}_2$ and $\underline{\underline{\mathbf{V}}}_3$ are the voltages of the conductors 1, 2 and 3 respectively, and

$$\underline{\underline{\mathbf{S}}}_{ii} = \frac{\ln(2h_i/r_i)}{2\pi\epsilon_0} \quad , \quad \underline{\underline{\mathbf{S}}}_{ij} = \underline{\underline{\mathbf{S}}}_{ji} = \frac{\ln(r_{ij}/r_{ij})}{2\pi\epsilon_0} \quad (i=1,2,3 \text{ and } j=1,2,3) \quad (2.10)$$

The factors h_i , r_i , r_{ij} and r_{ij} that appear in relation (2.10) are:

- h_i , distance of the conductor i from the ground
- r_i , radius of the conductor i
- r_{ij} , distance between the conductors i and j
- r_{ij} , distance between the conductor i and the j conductor's image.

Figure 1 shows, for example, three characteristic distances h_1 , r_{12} and $r_{1,2'}$.

The conductors' charges $\underline{\underline{\mathbf{Q}}}_1$, $\underline{\underline{\mathbf{Q}}}_2$ and $\underline{\underline{\mathbf{Q}}}_3$ constitute an asymmetrical system, which impedes the calculation of the intensity of the electric field. The asymmetrical system of charges is analyzed in three symmetrical three phase systems, the positive, the negative and the zero sequence system, according to relation (2.11).

$$\begin{bmatrix} \underline{\underline{\mathbf{Q}}}_{(0)} \\ \underline{\underline{\mathbf{Q}}}_{(1)} \\ \underline{\underline{\mathbf{Q}}}_{(2)} \end{bmatrix} = \frac{1}{3} \cdot \begin{bmatrix} 1 & 1 & 1 \\ 1 & \underline{\underline{\mathbf{a}}} & \underline{\underline{\mathbf{a}}}^2 \\ 1 & \underline{\underline{\mathbf{a}}}^2 & \underline{\underline{\mathbf{a}}} \end{bmatrix} \cdot \begin{bmatrix} \underline{\underline{\mathbf{Q}}}_1 \\ \underline{\underline{\mathbf{Q}}}_2 \\ \underline{\underline{\mathbf{Q}}}_3 \end{bmatrix} \quad (2.11)$$

where $\underline{\underline{\mathbf{Q}}}_{(0)}$, $\underline{\underline{\mathbf{Q}}}_{(1)}$, $\underline{\underline{\mathbf{Q}}}_{(2)}$ are the zero, the positive and the negative sequence charge respectively and $\underline{\underline{\mathbf{a}}} = e^{i2\pi/3}$.

The intensity of the electric field is calculated for each one of the components of charges separately and the final accurate formulas arise from the superimposition of the results.

3 Electric field of single circuit power lines with conductors in triangular arrangement

3.1 Accurate formula of the electric field

Figure 2 shows a single circuit line with the conductors placed on the corners of an equilateral triangle. The voltages of the three conductors constitute a symmetrical system and are given by relation (3.1).

$$V_a = V \angle 120^0 \quad , \quad V_b = V \angle 0^0 \quad , \quad V_c = V \angle -120^0 \quad (3.1)$$

Figure 2. Model of a single circuit power line with the conductors placed on the corners of an equilateral triangle

Choosing the center of the arrangement as the reference point for both the real conductors' system and the conductors' images' system, as shown in figure 2, the distances of the conductors from these points are given in (3.2).

$$\mathbf{d}_a = \mathbf{p} e^{j\frac{2\pi}{3}} \quad , \quad \mathbf{d}_b = \mathbf{p} \quad , \quad \mathbf{d}_c = \mathbf{p} e^{-j\frac{2\pi}{3}} \quad (3.2a)$$

$$\mathbf{d}'_a = \mathbf{p} e^{j\frac{\pi}{3}} \quad , \quad \mathbf{d}'_b = -\mathbf{p} \quad , \quad \mathbf{d}'_c = \mathbf{p} e^{-j\frac{\pi}{3}} \quad (3.2b)$$

where $\mathbf{p} = jp$ is the distance vector between the reference point O and the upper conductor, as shown in figure 2.

Due to $\mathbf{d}_k \neq \mathbf{d}'_k$, the moments $\underline{\mathbf{M}}_k$ and $\underline{\mathbf{M}}'_k$, which are given in relations (2.7), are different,

$$\underline{\mathbf{M}}_k \neq \underline{\mathbf{M}}'_k \quad (3.3)$$

From relation (3.3) results that the real conductors' system is calculated separately from the conductors' images' system.

The conductors' charges are calculated through relations (2.8)-(2.10) and the asymmetrical system that results is analyzed in its symmetrical components according to relation (2.11). For all the changes of the distance between the conductors as well as the height h from the ground of the real conductors, it results that the negative sequence charge is practically zero ($Q_{(2)}=0$) and that the charges' angles for the positive and zero sequence system, $\theta_{(1)}$ and $\theta_{(0)}$ respectively, remain constant and equal to

$$\theta_{(1)} = \frac{2\pi}{3}, \quad \theta_{(0)} = \pi \quad (3.4)$$

Thus, the intensity of the electric field is calculated only for the positive and zero sequence charges for the two conductors' systems (real conductors and conductors' images) separately.

Considering that the conductors bring only the positive sequence charges, then each conductor's charge is given in relation (3.5)

$$\underline{Q}_a = \underline{Q}_{(1)}, \quad \underline{Q}_b = \underline{a}^2 \underline{Q}_{(1)}, \quad \underline{Q}_c = \underline{a} \underline{Q}_{(1)} \quad (3.5)$$

where according to relation (3.4), results

$$\underline{Q}_{(1)} = Q_{(1)} \cdot e^{i\frac{2\pi}{3}} \quad (3.6)$$

Replacing relations (3.2), (3.5) and (3.6) in relations (2.7), (2.6) and (2.5) and taking into consideration relation (3.3), results the intensity of the electric field that comes from the positive sequence charge and is given in (3.7) for the conductors' images' system and in (3.8) for the real conductors' system.

$$\underline{E}'_{(1)} = - \frac{3Q_{(1)} \bar{\mathbf{p}}}{4\pi\epsilon_0 \left(\bar{\mathbf{R}}'^3 + \bar{\mathbf{p}}^3 \right)} \cdot \left[\bar{\mathbf{R}}' (1+ij) - \bar{\mathbf{p}} (1-ij) \right] \quad (3.7)$$

$$\underline{E}_{(1)} = - \frac{3Q_{(1)} \bar{\mathbf{p}}}{4\pi\epsilon_0 \left(\bar{\mathbf{R}}^3 - \bar{\mathbf{p}}^3 \right)} \cdot \left[\bar{\mathbf{R}} (1-ij) + \bar{\mathbf{p}} (1+ij) \right] \quad (3.8)$$

Considering that the conductors bring only the zero sequence charges, then each conductor's charge is given in relation (3.9)

$$\underline{Q}_a = \underline{Q}_{(0)}, \quad \underline{Q}_b = \underline{Q}_{(0)}, \quad \underline{Q}_c = \underline{Q}_{(0)} \quad (3.9)$$

where according to relation (3.4), results

$$\underline{Q}_{(0)} = Q_{(0)} \cdot e^{i\pi} \quad (3.10)$$

Replacing relations (3.2), (3.9) and (3.10) in relations (2.7), (2.6) and (2.5) and taking into consideration relation (3.3), results the intensity of the electric field that comes from the zero sequence charge and is given in (3.11) for the conductors' images' system and in (3.12) for the real conductors' system.

$$\underline{E}'_{(0)} = - \frac{6Q_{(0)} \bar{\mathbf{R}}'^2}{4\pi\epsilon_0 \left(\bar{\mathbf{R}}'^3 + \bar{\mathbf{p}}^3 \right)} \quad (3.11)$$

$$\underline{E}_{(0)} = \frac{6Q_{(0)} \bar{\mathbf{R}}^2}{4\pi\epsilon_0 \left(\bar{\mathbf{R}}^3 - \bar{\mathbf{p}}^3 \right)} \quad (3.12)$$

The intensity of the electric field \underline{E} , at any point in the vicinity of the line, arises finally from the

superimposition of all intensities from relations (3.7), (3.8), (3.11) and (3.12), as shown in (3.13).

$$\underline{E} = (\underline{E}_{(1)} + \underline{E}_{(0)}) + (\underline{E}'_{(1)} + \underline{E}'_{(0)}) \quad (3.13)$$

From (3.13), results the final expression (3.14), which represents the intensity of the electric field as a double complex number.

$$\begin{aligned} \underline{E} = & -\frac{3}{4\pi\epsilon_0 \left(\begin{smallmatrix} -3 & -3 \\ \mathbf{R} & -\mathbf{p} \end{smallmatrix} \right) \left(\begin{smallmatrix} -3 & -3 \\ \mathbf{R}' & +\mathbf{p} \end{smallmatrix} \right)} \cdot [(Q_{(1)} \begin{smallmatrix} -3 & -3 \\ \mathbf{p}\mathbf{R} & \mathbf{R}' \end{smallmatrix} + Q_{(1)} \begin{smallmatrix} -3 & -3 \\ \mathbf{p}\mathbf{R}\mathbf{R}' & \end{smallmatrix} - Q_{(1)} \begin{smallmatrix} -2 & -3 \\ \mathbf{p} & \mathbf{R} \end{smallmatrix} + Q_{(1)} \begin{smallmatrix} -2 & -3 \\ \mathbf{p} & \mathbf{R}' \end{smallmatrix} + 2Q_{(0)} \begin{smallmatrix} -3 & -2 \\ \mathbf{R} & \mathbf{R}' \end{smallmatrix} \\ & - 2Q_{(0)} \begin{smallmatrix} -2 & -3 \\ \mathbf{R} & \mathbf{R}' \end{smallmatrix} - Q_{(1)} \begin{smallmatrix} -4 & - \\ \mathbf{p} & \mathbf{R}' \end{smallmatrix} + Q_{(1)} \begin{smallmatrix} -4 & - \\ \mathbf{p} & \mathbf{R} \end{smallmatrix} + 2Q_{(1)} \begin{smallmatrix} -5 & \\ \mathbf{p} & \end{smallmatrix} - 2Q_{(0)} \begin{smallmatrix} -3 & -2 \\ \mathbf{p} & \mathbf{R}' \end{smallmatrix} - 2Q_{(0)} \begin{smallmatrix} -3 & -2 \\ \mathbf{p} & \mathbf{R} \end{smallmatrix}) + \\ & + ij(Q_{(1)} \begin{smallmatrix} -3 & -3 \\ \mathbf{p}\mathbf{R} & \mathbf{R}' \end{smallmatrix} + Q_{(1)} \begin{smallmatrix} -2 & -3 \\ \mathbf{p} & \mathbf{R} \end{smallmatrix} - Q_{(1)} \begin{smallmatrix} -4 & - \\ \mathbf{p} & \mathbf{R}' \end{smallmatrix} - Q_{(1)} \begin{smallmatrix} -3 & -3 \\ \mathbf{p}\mathbf{R}\mathbf{R}' & \end{smallmatrix} + Q_{(1)} \begin{smallmatrix} -2 & -3 \\ \mathbf{p} & \mathbf{R}' \end{smallmatrix} - Q_{(1)} \begin{smallmatrix} -4 & - \\ \mathbf{p} & \mathbf{R} \end{smallmatrix})] \end{aligned} \quad (3.14)$$

The rms value of the electric field E is equal to the modulus of the double complex number \underline{E} and is given in relation (3.15).

$$\begin{aligned} E = & \frac{3\sqrt{2}}{4\pi\epsilon_0} \cdot \left[\frac{1}{\left(\mathbf{R}^6 + \mathbf{p}^6 - 2\mathbf{R}^3\mathbf{p}^3\sin 3\theta_{\mathbf{R}} \right) \left(\mathbf{R}'^6 + \mathbf{p}^6 - 2\mathbf{R}'^3\mathbf{p}^3\sin 3\theta_{\mathbf{R}'} \right)} \right]^{1/2} \cdot \\ & [(Q_{(1)}\mathbf{p}\mathbf{R}^3\mathbf{R}'\sin(3\theta_{\mathbf{R}} - \theta_{\mathbf{R}'}) - Q_{(1)}\mathbf{p}^2\mathbf{R}^3\cos 3\theta_{\mathbf{R}'} - Q_{(1)}\mathbf{p}^4\mathbf{R}'\cos\theta_{\mathbf{R}'} + Q_{(0)}\mathbf{R}^3\mathbf{R}'^2\cos(3\theta_{\mathbf{R}} - 2\theta_{\mathbf{R}'}) \\ & - Q_{(0)}\mathbf{R}^2\mathbf{R}'^3\cos(2\theta_{\mathbf{R}} - 3\theta_{\mathbf{R}'}) - Q_{(0)}\mathbf{p}^3\mathbf{R}'^2\sin 2\theta_{\mathbf{R}'} + Q_{(0)}\mathbf{p}^3\mathbf{R}^2\sin 2\theta_{\mathbf{R}})^2 + \\ & + (Q_{(1)}\mathbf{p}\mathbf{R}\mathbf{R}'^3\sin(\theta_{\mathbf{R}} - 3\theta_{\mathbf{R}'}) + Q_{(1)}\mathbf{p}^2\mathbf{R}^3\cos 3\theta_{\mathbf{R}} + Q_{(1)}\mathbf{p}^4\mathbf{R}\cos\theta_{\mathbf{R}} + Q_{(0)}\mathbf{R}^3\mathbf{R}'^2\cos(3\theta_{\mathbf{R}} - 2\theta_{\mathbf{R}'}) \\ & - Q_{(0)}\mathbf{R}^2\mathbf{R}'^3\cos(2\theta_{\mathbf{R}} - 3\theta_{\mathbf{R}'}) - Q_{(0)}\mathbf{p}^3\mathbf{R}'^2\sin 2\theta_{\mathbf{R}'} + Q_{(0)}\mathbf{p}^3\mathbf{R}^2\sin 2\theta_{\mathbf{R}})^2 + \\ & + (-Q_{(1)}\mathbf{p}\mathbf{R}^3\mathbf{R}'\cos(3\theta_{\mathbf{R}} - \theta_{\mathbf{R}'}) + Q_{(1)}\mathbf{p}^2\mathbf{R}'^3\sin 3\theta_{\mathbf{R}'} + Q_{(1)}\mathbf{p}^4\mathbf{R}'\sin\theta_{\mathbf{R}'} - Q_{(1)}\mathbf{p}^5 + Q_{(0)}\mathbf{R}^3\mathbf{R}'^2\sin(3\theta_{\mathbf{R}} - 2\theta_{\mathbf{R}'}) \\ & - Q_{(0)}\mathbf{R}^2\mathbf{R}'^3\sin(2\theta_{\mathbf{R}} - 3\theta_{\mathbf{R}'}) - Q_{(0)}\mathbf{p}^3\mathbf{R}'^2\cos 2\theta_{\mathbf{R}'} - Q_{(0)}\mathbf{p}^3\mathbf{R}^2\cos 2\theta_{\mathbf{R}})^2 + \\ & + (-Q_{(1)}\mathbf{p}\mathbf{R}\mathbf{R}'^3\cos(\theta_{\mathbf{R}} - 3\theta_{\mathbf{R}'}) + Q_{(1)}\mathbf{p}^2\mathbf{R}^3\sin 3\theta_{\mathbf{R}} + Q_{(1)}\mathbf{p}^4\mathbf{R}\sin\theta_{\mathbf{R}} - Q_{(1)}\mathbf{p}^5 + Q_{(0)}\mathbf{R}^3\mathbf{R}'^2\sin(3\theta_{\mathbf{R}} - 2\theta_{\mathbf{R}'}) \\ & - Q_{(0)}\mathbf{R}^2\mathbf{R}'^3\sin(2\theta_{\mathbf{R}} - 3\theta_{\mathbf{R}'}) - Q_{(0)}\mathbf{p}^3\mathbf{R}'^2\cos 2\theta_{\mathbf{R}'} + Q_{(0)}\mathbf{p}^3\mathbf{R}^2\cos 2\theta_{\mathbf{R}})^2]^{1/2} \end{aligned} \quad (3.15)$$

The angles $\theta_{\mathbf{R}}$ and $\theta_{\mathbf{R}'}$ are shown in figure 2. Relation (3.15) is valid only for the case where the equilateral triangle has the arrangement of figure 2. If the triangle has a different placement in space, then the relative positions of the images would also be different and the calculation of the intensity of the electric field should remade from the beginning.

3.2 Approximate formulas of the electric field

Relation (3.15) is the accurate formula of the intensity of the electric field and depends on the positive and zero sequence charges. This formula is very extensive. A simpler approximate formula may derive taking into account only one of the symmetrical components of the charges.

Figure 3 shows the effect of the positive and zero sequence charge in the intensity of the electric field, for a typical 150kV power line with the conductors in triangular arrangement. From figure 3 results that the positive sequence charge has the bigger effect in the electric field not only close to but also far from the line. However, choosing only the positive sequence charge for the calculation of the electric field, the deviation from the accurate values, mainly close to the line, is considerable.

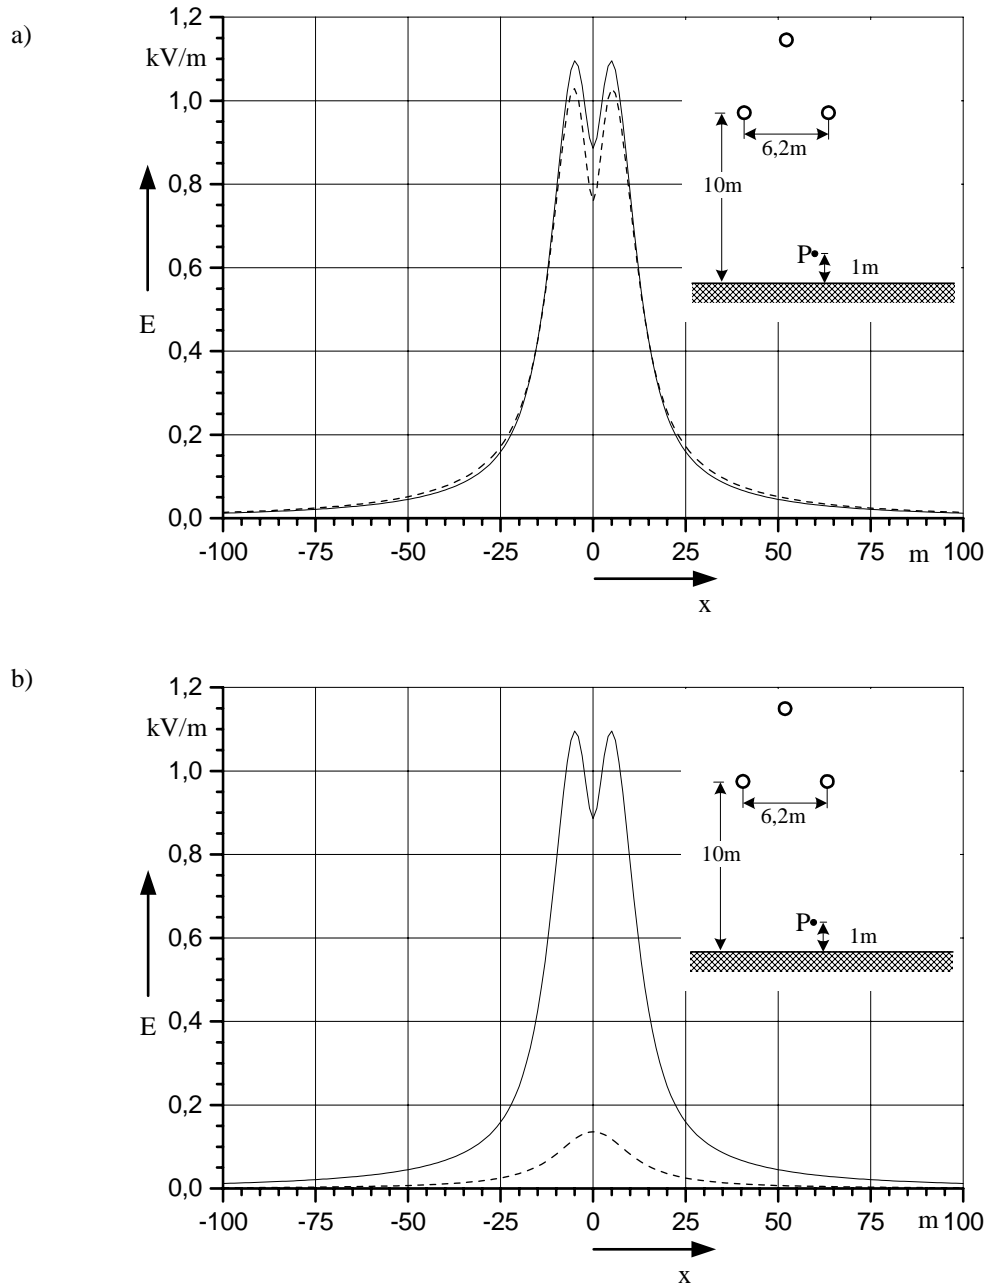

Figure 3. a) Positive and b) zero sequence charge effect in the electric field E that produced by a typical 150kV single circuit line with triangular arrangement of conductors.

————— Accurate values by formula (3.15) - - - - - Symmetrical component's effect

Replacing $Q_{(0)}=0$ in (3.15), the intensity of the electric field by the positive sequence charge is derived in (3.16).

$$E = \frac{3\sqrt{2}Q_{(1)}P}{4\pi\epsilon_0} \cdot \left[\frac{1}{(R^6 + p^6 - 2R^3 p^3 \sin 3\theta_R)(R'^6 + p'^6 - 2R'^3 p'^3 \sin 3\theta_{R'})} \right]^{1/2} \cdot$$

$$\left[(R^3 R' \sin(3\theta_R - \theta_{R'}) - p R^3 \cos 3\theta_R - p^3 R' \cos \theta_{R'})^2 + (R R^3 \sin(\theta_R - 3\theta_{R'}) + p R^3 \cos 3\theta_R + p^3 R \cos \theta_R)^2 + \right.$$

$$\left. + (-R^3 R' \cos(3\theta_R - \theta_{R'}) + p R^3 \sin 3\theta_R + p^3 R' \sin \theta_{R'} - p^4)^2 + (-R R^3 \cos(\theta_R - 3\theta_{R'}) + p R^3 \sin 3\theta_R + p^3 R \sin \theta_R - p^4)^2 \right]^{1/2} \quad (3.16)$$

Relation (3.16) is also quite extensive. Taking into account the considerable deviation between the approximate values and the accurate values of the electric field, it results that the approximate formula (3.16) is not efficient.

Another formula may derive considering $R=R'$ and $\theta_R=\theta_{R'}$. Thus, replacing $R=R'$ and $\theta_R=\theta_{R'}$ in (3.15), the simpler formula (3.17) arises.

$$E = \frac{3}{2\pi\epsilon_0} \cdot \frac{1}{R^6 + p^6 - 2R^3 p^3 \sin 3\theta_R} \cdot [Q_{(1)}^2 p^2 (R^4 \sin 2\theta_R - p R^3 \cos 3\theta_R - p^3 R \cos \theta_R)^2 + (-Q_{(1)} p R^4 \cos 2\theta_R + Q_{(1)} p^2 R^3 \sin 3\theta_R + Q_{(1)} p^4 R \sin \theta_R - Q_{(1)} p^5 + 2Q_{(0)} R^5 \sin \theta_R - 2Q_{(0)} p^3 R^2 \cos 2\theta_R)^2]^{1/2} \quad (3.17)$$

Relation (3.17) is the accurate formula of the intensity of the electric field on the surface of ground. This relation can also be a very good approximate formula for the electric field, for low calculation heights (up to 1m), as well as for far distances from the line.

Figure 4 shows the comparison of the electric field E produced by a single circuit line with the conductors in triangular arrangement, as it is calculated by the accurate formula (3.15) and the approximate formula (3.17). In figure 4a the comparison between the two formulas is made for calculation height 1m from the ground, while in figure 4b the comparison is made for calculation height 3m from it.

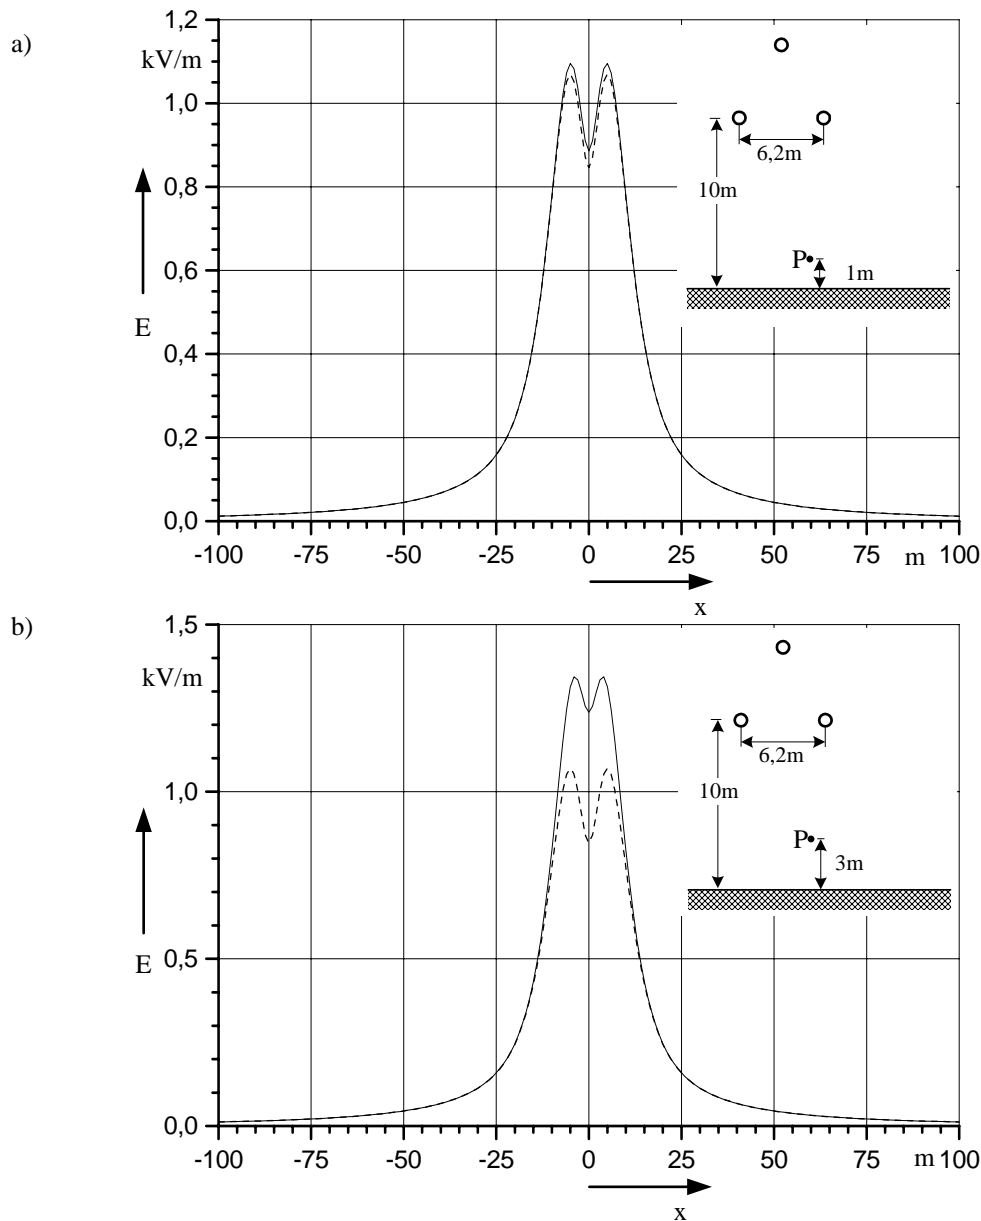

Figure 4. Intensity of the electric field E produced by a typical 150kV single circuit line with triangular arrangement of the conductors, as it is calculated from the accurate formula (3.15) and the approximate formula (3.17) for height a) 1m and b) 3m from the ground.

————— Accurate formula (3.15) - - - - - Approximate formula (3.17)

Figure 4a shows that for low calculation heights (up to 1m), the approximate formula (3.17) gives the intensity of the electric field with exceptional precision, not only far from the line, but also close to it. Figure 4b shows that for bigger calculation heights, the formula (3.17) gives satisfying results only for far distances from the line, while close to it the deviation is significant.

4 Conclusions

The electric field produced by power lines of big length in comparison with the distances between the conductors and the distances between the conductors and the ground, can be expressed with extensive analytical formulas. In the present paper a method to derive the analytical formulas of the electric field has been developed. This method is based on the analysis of the intensity of the electric field into two multipole expansions, one from the real conductors' system and the other from the conductors' images' system. For the simplification of the mathematical expressions double complex numbers are used. Due to the asymmetry of conductors' charges, they are analyzed in their symmetrical components.

Using this method the accurate analytical formula for the intensity of the electric field produced by single circuit lines with the conductors in triangular arrangement is given. This relation may be used for the accurate calculation of the intensity of the electric field, at any point in the vicinity of the lines, close to or far from them. From the accurate formula, a simpler approximate formula with very good precision is derived, which is valid either for low calculation heights (up to 1m) either for bigger heights in far distances from the line.

Abstract

In this paper we discuss the human exposure level for electric and magnetic fields generated by power lines. In particular, we consider the real case of a populated area in Tuscany (Italy) crossed by two high voltage (380 kV) power lines. We carried out a wide measurement campaign and also estimated the electric and magnetic fields generated by the power lines by means of simple and full-wave models (based on the Method of Moments).

The measurement data are used to verify the accuracy of the models. The estimated electric and magnetic fields are then used to evaluate the field exposure in the whole area.

In this paper, we briefly describe the models used in the analysis. We then compare and examine the results obtained from the measurements and the models. Finally, we discuss the model exploitation.

Introduction

The problem of evaluating the power line field exposure is complicated for two reasons. The strong variation of the electric current in a power line reflects on the variation of the generated magnetic field, and the accurate estimation of the electric field generated by a power line can be a very complicated problem due to the complexity of the environment. If the area to be analyzed is large (in our case about $700 \text{ m} \times 250 \text{ m}$) an accurate evaluation of the human exposure level only by measures can be impracticable. Moreover, in case of evaluation of the exposure level for the magnetic field, it is necessary to analyze the field over a large time span (several months – one year). Even for this reason an accurate evaluation of the human exposure level only by measures can be impracticable. On the contrary, the combined utilization of measurements and numerical models allows the characterization of the electric and magnetic fields generated by power lines and the evaluation of the field exposure.

In Italy, the electric and magnetic fields generated by power lines are subjected to the D.P.C.M. (Decree of the Prime Minister) 8th July 2003. It states that the maximum electric field generated by power lines (in accessible areas) has not to exceed the effective value of 5 kV/m. For the effective value of the magnetic flux density (here, for sake of brevity, the magnetic field), the D.P.C.M. establishes three limits. The maximum value has not to exceed 100 μT . In babies playing fields, schools, houses and, in general, in areas where people can stay more than 4 hours/day, the value of 10 μT , evaluated as median over a time span of 24 hours, has not to be exceeded. Finally, in case of a new power line near babies playing fields, schools, houses and, in general, in areas where people can stay more than 4 hours/day, and/or new buildings the median value of 3 μT has not to be exceeded.

The fact to have to evaluate the median value of the magnetic field over 24 hours makes hard to carry out a measurement campaign in a large area. The Italian regulations CEI 211-6 gives suggestions about a measurement campaign and allow the use of a numerical model, recommending measurements where a numerical model estimates a field intensity greater than 50% of the limit value. In our case we have collected a large measurement set (one hundred points / two heights for point / two dates per point), we have used these data in order to evaluate the numerical model accuracy, and we have used the numerical model to estimate the human

exposure level [1], [2].

The Italian regulations CEI 211-4 describes two models (for the magnetic and electric field, respectively) to estimate the fields generated by power lines. These models are two-dimensional, i.e. consider the two-dimensional problem obtained from a perpendicular plane cut of the power line, containing the test point. In order to estimate the magnetic field, the terrain is considered completely transparent, so the Biot-Savart law for a infinite straight wire can be directly used. In order to estimate the electric field, the terrain is assumed as an infinite plane parallel to the power line wires and with an electric potential of 0 V. In order to use these (and the others) numerical models, we have collected all the geometrical and electrical characteristics of the power lines, including the line current and voltage recording (one sample per hour for one year).

We have also used others models, to represent in more detail the real situation. In particular, we have used a three dimensional Biot-Savart model in order to estimate the magnetic field, and a 2D full wave model, based on the Method of Moments [3], in order to estimate the electric field. In this model the profile of the terrain and of buildings on the plane perpendicular to the power line wires and containing the test points are considered at 0 V and are discretized by linear segments with an unknown uniform electric charge distributed on. Also, a three dimensional model is considered, where the AIM (Adaptive Integral Method) [4], [5] approach is used to overcome the computational time and dynamic memory requests of the classical Method of Moments in case of a large number of unknowns.

In the following sections we briefly described the models used, comparing the results with the measurements.

Magnetic field model

We have used two numerical models to estimate the magnetic field generated by power lines. Both models use the Biot-Savart law, in two and three dimensions, respectively. In the following, we describe these models and the results obtained.

Two dimensional model

The two dimensional model follows the Italian regulations CEI 211-4. The fields are considered almost static, the wires of the power lines are assumed as infinite straight wires with uniform current and passing by the intersection between the real wire and the perpendicular plane containing the test point. The terrain and other objects (buildings, etc.) are considered having the same magnetic permeability of the air. So, they are completely transparent to the magnetic field and the classical Biot-Savart law can be employed to evaluate the contribution of a wire to the total magnetic field. This situation is sketched in Fig. 1.

The magnetic field generated by the power line is given by

$$\vec{B}(\vec{r}) = \sum_{i=1}^M \vec{B}_i(\vec{r}) = \frac{\mu}{2\pi} \sum_{i=1}^M I_i \frac{\hat{u}_i}{d_i} ,$$

where M is the number of wires, I_i is the current phasor flowing on wire i , d_i is the distance between the wire i and the test point on the plane perpendicular to the wire, and

$$\hat{u}_i = \hat{x} \times \hat{d}_i = \hat{x} \times \frac{\vec{d}_i}{d_i} .$$

Fig. 1: Two dimensional model geometry for the evaluation of the magnetic field.

Respect to the CEI 211-4 specifications, in the two dimensional model the effect of the terrain has been considered through image wires (with current $-I_i$), placed at an height

$$h'_i = h_i + 503 \sqrt{2\rho_g/f_0} \exp(j\pi/4)$$

below the terrain, where h_i is the height of the wire i respect to the terrain, f_0 is the frequency and ρ_g is the mean resistivity of the terrain [6]. However, in our case ($\rho_g = 8 \Omega \text{ m}$), we have found that the contribution of the images of the real wires is not so significant.

Three dimensional model

In the three dimensional model, with respect to the two dimensional model, the real wires of the power lines are represented as a sequence of linear segments. Moreover, the images of the real wires are not considered. With reference to Fig. 2, the contribution to the magnetic field given by the segment $\overrightarrow{P_1 P_2}$ is

$$\vec{B}_{\overrightarrow{P_1 P_2}}(\vec{r}) = \frac{\mu}{4\pi} I \int_{P_1}^{P_2} \frac{\hat{s} \times \hat{r}}{r^2} dl = \frac{\mu}{4\pi} I \hat{u} \int_{P_1}^{P_2} \frac{\sin(\theta)}{r^2} dl = \frac{\mu}{4\pi d} I \hat{u} (\cos(\theta_1) - \cos(\theta_2)),$$

with $\hat{u} = \hat{s} \times \hat{r}$. The overall magnetic field generated by a power line, with M wires subdivided in N segments, is

$$\vec{B}(\vec{r}) = \frac{\mu}{4\pi} \sum_{i=1}^M I_i \left[\sum_{j=0}^{N+1} \frac{\hat{u}_{i,j}}{d_{i,j}} (\cos(\theta_{i,j}) - \cos(\theta_{i,j+1})) \right].$$

Outside the region of interest, the wires are approximated with two semi-infinite segments, so

$$\theta_{i,0} = 0 \quad \theta_{i,N+2} = \pi.$$

Results

In Fig. 3 we show a comparison result for the two and the three dimensional model. In every point we have measured the magnetic field 2 m over the floor. Besides the estimated value, an error bar representing the maximum and minimum values relative to an uncertainty of 2 m in the position is showed. The area is near a power line tower, that is the worse situation respect to the straight wire approximation assumed in the two dimensional model. In spite of this, we see that the two dimensional model can be used to verify the Italian regulations compliance of power lines, even if the three dimensional model has higher accuracy and almost the same implementation complexity.

Using a numerical model and the power line current recording we can characterize the magnetic field generated by the power line. Besides contour maps, a product obtainable with a numerical model is shown in Fig. 4.

Fig. 2: Three dimensional model geometry for the evaluation of the magnetic field.

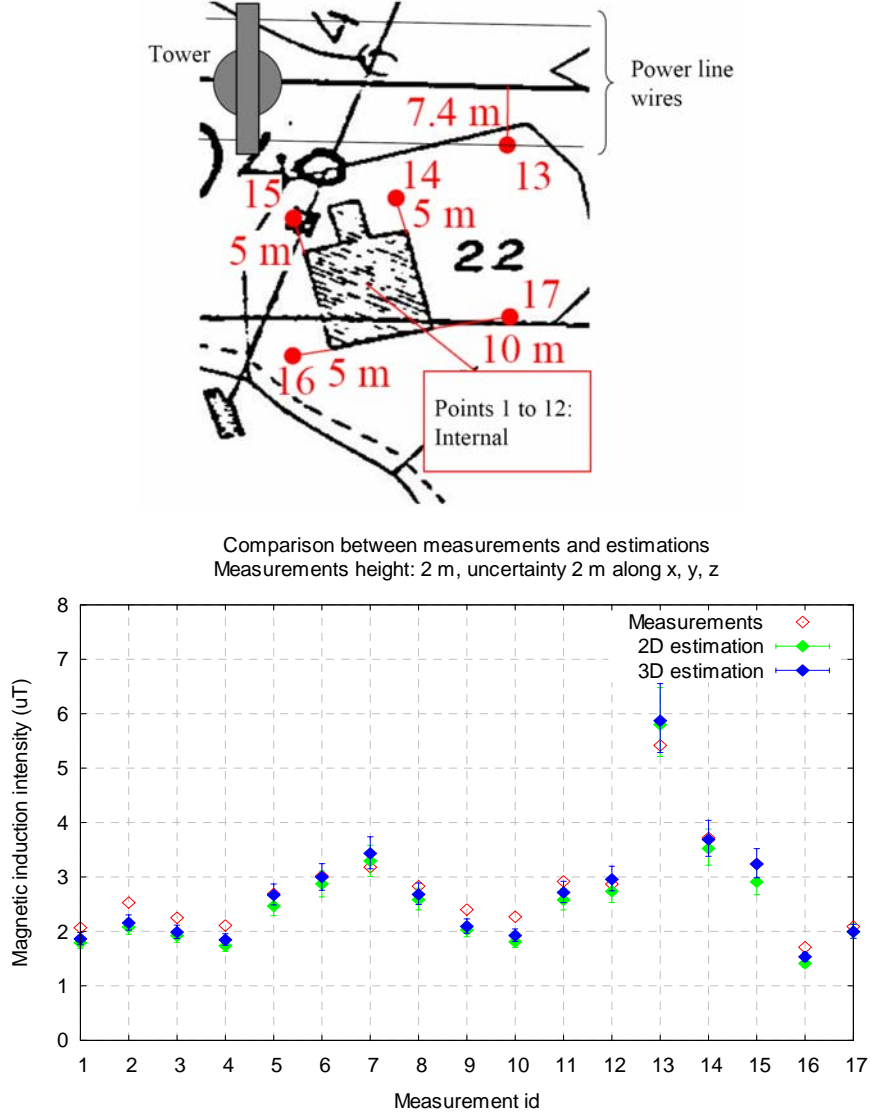

Fig. 3: Comparison between the two and three dimensional model results. Up: position of the measurement points. Down: comparison results. The estimated values are indicated by diamonds. The error bars are relative to assuming a topography and position accuracy of 2 meters.

Electric field model

We have used two 2D models to estimate the electric field generated by power lines. The first one is the model indicated by the Italian regulations CEI 211-4. The second one includes the topography and buildings effects, and is based on the Methods of Moments with pulse basis functions and point matching. We also discuss the 3D extension of the last model, using the AIM formulation in order to reduce the computational complexity of the algorithm. In the following, we describe these models and the results obtained with the 2D models. Results obtained with the 3D AIM model will be shown at the conference.

CEI 211-4 model

As sketched in Fig. 5, the CEI 211-4 numerical model for the electric field generated by power line is the simplest one. The wires of the power line are assumed infinitely straight and parallel, the terrain is assumed perfectly flat and at 0 V potential.

In this case, the electric charge q_i on wire i is obtainable solving the linear system $\underline{V} = \underline{S}\underline{Q}$, where \underline{Q} and $\underline{V} = [\psi_i - \psi_0 = \psi_i]$ are the vector containing the electric charge and the voltage of the wires, respectively, and the elements of the elastance matrix \underline{S} are given by

Fig. 4: Median value histogram (left) and graph (right) of the magnetic field as evaluated by the numerical model. The value of 3 μT is the limit indicated by the Italian regulations for a new plant or building.

Fig. 5: CEI 211-4 electric field model geometry.

$$s_{ij} = \frac{1}{2\pi\epsilon} \ln \left(\frac{d'_{ij}}{d_{ij}} \right).$$

When the electric charges are determined, the electric field follows

$$\vec{E}(\vec{\rho}) = \frac{1}{2\pi\epsilon} \sum_{i=1}^M q_i \frac{\vec{\rho} - \vec{\rho}_i}{|\vec{\rho} - \vec{\rho}_i|^2} - \frac{1}{2\pi\epsilon} \sum_{i=1}^M q_i \frac{\vec{\rho} - \vec{\rho}'_i}{|\vec{\rho} - \vec{\rho}'_i|^2},$$

where a primed quantity denotes the position of an image and M is the number of wires.

Full 2D model

The full 2D model includes the presence of building and a not flat terrain, as sketched in Fig. 6. It employs a Method of Moments using pulse basis functions to describe the buildings and the terrain, and the point matching technique.

The electric charge on the wires and the amplitude of the linear charge distribution on the segments are again evaluated solving the linear system $\underline{V} = \underline{S}\underline{Q}$, where the first M elements of the vectors \underline{Q} and \underline{V} are the charge and the voltage of the wires, respectively, and the remaining ones are the amplitude of the linear charge distribution and the voltage (0 V) of the N_s segments representing the buildings and the terrain. The elements of the elastance matrix \underline{S} are now given by

$$s_{ij} = \begin{cases} \frac{1}{2\pi\epsilon} \ln \left(\frac{d'_{ij}}{d_{ij}} \right) & \text{for } 1 \leq j \leq M \\ \frac{T'_{ij} - T_{ij}}{2\pi\epsilon} & \text{for } M+1 \leq j \leq M+N_s \end{cases}$$

where

$$T_{ij} = \frac{1}{L_j} \int_{-L_j/2}^{L_j/2} \ln \left| \vec{\rho}_i - \vec{\rho}_j - \ell \hat{\ell}_j \right| d\ell$$

$$T'_{ij} = \frac{1}{L_j} \int_{-L_j/2}^{L_j/2} \ln \left| \vec{\rho}_i - \vec{\rho}'_j - \ell \hat{\ell}'_j \right| d\ell$$

and L_j is the length of segment j , $\hat{\ell}_j$ is its direction, $\vec{\rho}_i$ and $\vec{\rho}_j$ are the position of the wire i and of the center of segment j , respectively. The electric field is then evaluated as

$$\vec{E}(\vec{\rho}) = \frac{1}{2\pi\epsilon} \sum_{i=1}^M q_i \frac{\vec{\rho} - \vec{\rho}_i}{|\vec{\rho} - \vec{\rho}_i|^2} - \frac{1}{2\pi\epsilon} \sum_{i=1}^M q_i \frac{\vec{\rho} - \vec{\rho}'_i}{|\vec{\rho} - \vec{\rho}'_i|^2} +$$

$$+ \frac{1}{2\pi\epsilon} \sum_{i=M+1}^{M+N_s} \frac{q_i}{L_i} \int_{-L_i/2}^{L_i/2} \frac{\vec{\rho} - \vec{\rho}_i - \ell \hat{\ell}_i}{|\vec{\rho} - \vec{\rho}_i - \ell \hat{\ell}_i|^2} d\ell - \frac{1}{2\pi\epsilon} \sum_{i=M+1}^{M+N_s} \frac{q_i}{L_i} \int_{-L_i/2}^{L_i/2} \frac{\vec{\rho} - \vec{\rho}'_i - \ell \hat{\ell}'_i}{|\vec{\rho} - \vec{\rho}'_i - \ell \hat{\ell}'_i|^2} d\ell,$$

where the primed entities are relative to the images.

Results

In Fig. 7 we show the comparison between measurements and estimations for two transverse sections respect to the power line in the area under analysis. We consider the presence of the buildings, but do not consider the other obstacles (trees, etc.). This is not enough to obtain a good accuracy. However, the model can give some information about the position of the points where measure the electric field. The power line voltage is almost constant, so we can characterize the electric field generated by the power line by such measurements.

In order to obtain a better accuracy, we can model the power line and the buildings in three dimensions. This brings to increase the number of basis functions, leading the application of the Method of Moments to an unfeasible requests on computational time and/or dynamic memory. An efficient method can be adopted, and in the following we discuss about the use of the AIM formulation in the 3D problem corresponding to the geometry sketched in Fig. 6.

On the use of Adaptive Integral Method

A three dimensional analysis of the area of interest through the Method of Moments to estimate the electric field generated by a power line could be more accurate than a the 2D model, but it leads to unfeasible requests on computational time and/or dynamic memory. In such case the use of a computationally efficient scheme of the Method of Moments gives the opportunity to carry out a 3D analysis. In the following we discuss some implementation notes of the Adaptive Integral Method (AIM). Some results will be presented at the conference.

The Adaptive Integral Method (AIM) [4], [5] has been widely used to solve electromagnetic scattering and radiation problems involving large objects. Its implementation in a Method of Moments (MoM) approach allows, when used with an iterative solver, to accelerate the matrix-vector multiplication and to reduce the number of matrix elements to be stored. In particular, the computational complexity of a matrix-vector multiplication is in the order of $O(N^2)$ using the conventional MoM, where N is the number of unknowns, but using the AIM reduces it to $O(N^{1.5} \log N)$ and $O(N \log N)$ for surface and volume scattering, respectively.

The AIM exploits the convolutional property of the free space Green's function. In particular, the interaction between the basis and the testing functions are divided into near and far interactions. The near-interactions matrix elements are evaluated as in the conventional MoM. The other elements (far-interactions matrix elements) are approximated using an auxiliary set of basis function, placed on a uniform cartesian grid. Such auxiliary set of basis function are almost equivalent to the MoM basis function with reference to the elastance matrix elements [5]. By virtue of the auxiliary function are placed on an uniform cartesian grid, and due to the convolutional form of the free space Green's function, the matrix-vector product relative to the far-interactions matrix elements can efficiently evaluated through Fast Fourier Transforms (FFT's).

In case of a half-space limited by a perfectly conductor plane (Fig. 6, extended to three dimensions), the pertinent Green's function doesn't exhibit a convolutional form, so the AIM formulation cannot be applied directly. However, we can exploit the image principle and apply the AIM formulation on the actual object and on its image, increasing the number of points of the uniform cartesian grid to be considered. On the contrary, we can individually consider the real and the image term in the Green's function. In such case, the reflected term exhibits a correlation form on a space variable and its matrix-vector product contribution can be again evaluated by FFT's without increase the number of points of the uniform cartesian grid.

In particular, the needed direct FFT's samples can be obtained from the direct FFT's samples of the auxiliary basis functions of the real objects, obtaining an algorithm with almost the same computational complexity and

dynamic memory requested by the algorithm for the analysis of the object in free space.

In our implementation, the AIM formulation is applied only to the terrain and buildings. The wires of the power line (few unknowns) are considered as in the classical MoM, in order to reduce the number of FFT points along the z direction.

Assumed the ground plane at $z = 0$ position, the Green's function has the form

$$g_d(\vec{\rho} - \vec{\rho}', z - z') + g_i(\vec{\rho} - \vec{\rho}', z + z') = \frac{1}{4\pi\epsilon\sqrt{|\vec{\rho} - \vec{\rho}'|^2 + (z - z')^2}} - \frac{1}{4\pi\epsilon\sqrt{|\vec{\rho} - \vec{\rho}'|^2 + (z + z')^2}},$$

where $|\vec{\rho} - \vec{\rho}'|$ is the distance between source and test position in the xy plane. Considering the unknowns images, we have to evaluate

$$\sum_{p'=0}^{N_x-1} \sum_{q'=0}^{N_y-1} \sum_{r'=0}^{N_z-1} g_i((p-p')\delta_x, (q-q')\delta_y, 2h_z + (r-r')\delta_z) \psi(p', q', r') = g_i(p\delta_x, q\delta_y, 2h_z + r\delta_z) \otimes \psi(p, q, -r),$$

where \otimes denotes the three-dimensional convolution, $\delta_{x,y,z}$ denote the cartesian grid spacing along the x , y and z , respectively, h_z is the minimum z coordinate of the cartesian grid enclosing the object (0 in our case), and ψ denotes the auxiliary source values.

If $\Psi(i, j, k)$ denotes the FFT samples of $\psi(p, q, r)$, the FFT samples of $\psi(p, q, -r)$ are given by $\Psi(i, j, -k) = \Psi(i, j, \bar{N}_z - k)$, being \bar{N}_z the number of FFT points along the z direction.

So, the presence of image sources involves only the multiplication in the transformed domain. The overall computational complexity is dominated by the number of operations required by the direct and inverse FFT and it is almost the same of the free-space case. With similar consideration we can apply the AIM technique also in structure with one or more ground planes, parallel to the coordinate's planes. Such consideration can be useful in evaluation of capacitance for an arbitrary shaped three dimensional structure in the presence of such ground planes.

Conclusions

We have discussed about the use of numerical models of electric and magnetic fields generated by power lines to evaluate the human exposure level. The results obtained from numerical models are been compared to measurements. In case of the magnetic field, a 3D model can be efficiently used, with almost the same complexity of a 2D model. In case of electric field, a 2D numerical model hasn't a good accuracy, even consider the effects of buildings and topography, and measurements are necessary. In such case, a numerical model can be used to choose the measurement's points.

A 3D model can increase the accuracy. We have given some implementation notes about such model (AIM). Results will be shown at the conference.

Fig. 6: Full 2D electric field model geometry.

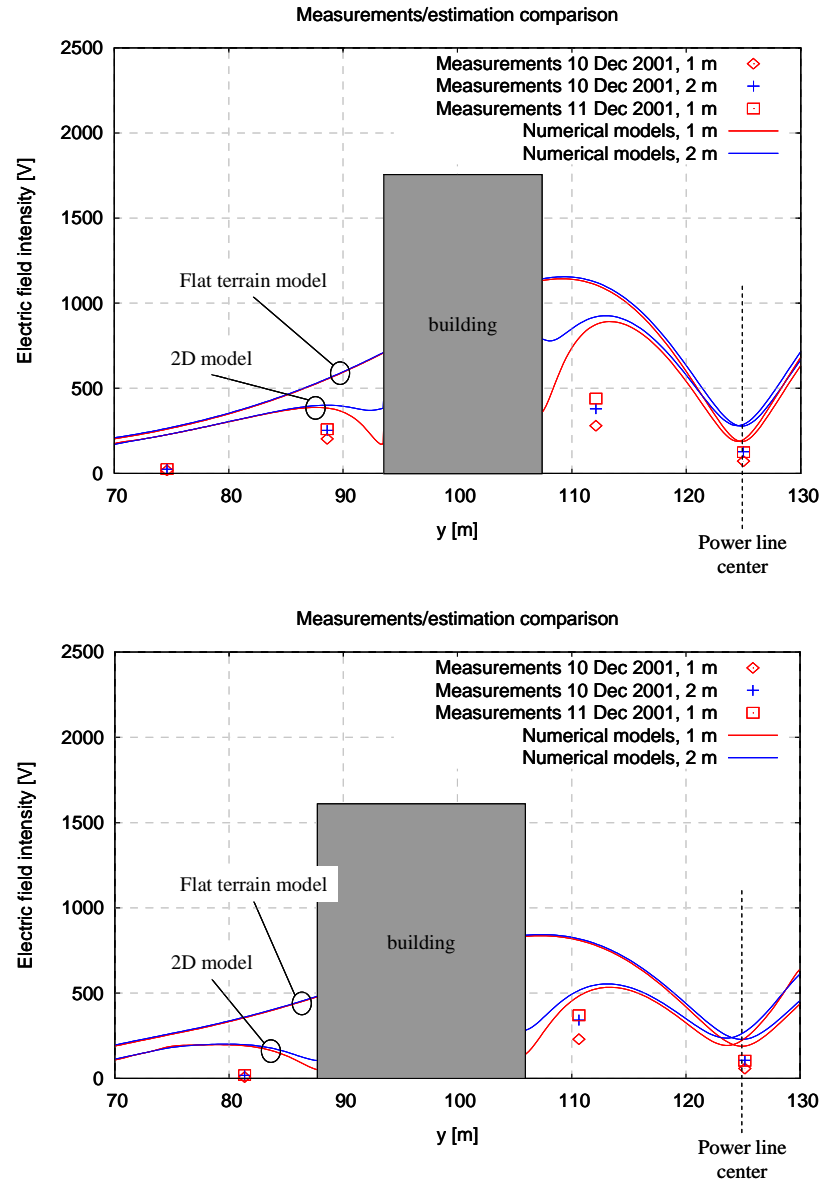

Fig. 7: Comparison between flat terrain and full 2D model results. Two different transverse sections respect to the power line are considered. The number in the legends refers to the quote of the test point.

Overview of IEEE / ISO 11073 RF Wireless: Point-of-care medical device communication – Transport Profiles – Guidelines for the use of RF wireless technology

Joseph J Morrissey

Motorola Labs, 8000 West Sunrise Blvd, Ft. Lauderdale, FL 33322

Abstract: The IEEE / ISO 11073 RF wireless series of standards provides an overview and analysis of the issues related to the use of radio frequency (RF) wireless technology for the transport of data both to and from point-of-care (PoC) medical devices. Currently, several different RF wireless technologies exist that might be applicable, each with different capabilities, stages of maturity in terms of standardization, and active implementation in medical devices and healthcare facilities. It is recognized that RF technologies are rapidly evolving, and new options may become available (or sufficiently established) in the near future offering additional (perhaps superior) solutions for PoC medical device data transport needs. Therefore, the IEEE / ISO 11073 RF wireless series of standards avoids being overly prescriptive but instead aims to assist end users in identifying the necessary requirements and considerations to select an appropriate RF wireless technology solution. Guidance is offered with the objective of allowing medical device manufacturers, wireless equipment manufacturers, healthcare providers, government agencies and any other stakeholders to make reasonable judgments regarding the performance and practical implementation of wireless solutions.

Introduction: Incorporation of wireless technology into point of care (PoC) medical devices has the potential to offer significant benefits to healthcare, specifically home- and mobile- based disease management. An initial IEEE / ISO 11073-30500 Framework and Overview standard outlines use case scenarios to estimate, compare, and contrast the performance of known technologies operating on personal area (WPAN), local area (WLAN), metropolitan area (WMAN), regional area (WRAN), and wide area (WWAN) networks. Major considerations in evaluating performance are 1) the physical requirements of data transport, 2) the quality of service (QoS) requirements associated with the data being transported, and 3) the capabilities of the wireless system. Also considered are related issues such as network architecture, EMI/EMC, co-existence with other data streams, security, cost, power consumption, and technology configurability. Such comparisons are not necessarily intended to endorse an optimal solution, because widely different needs, resources, sizes, and environments associated with healthcare facilities may have a large influence on determining appropriate solutions.

Understanding how these wireless technologies support different quality of service (QoS) requirements (reliability, latency, priority, bandwidth) and how transmit power, link range, battery life and other characteristic features are related to performance is essential [Figure 1]. Optimal performance will largely depend upon the criticality of the medical data and the specific needs and resources of the end user. Related issues include network architecture, EMI/EMC, co-existence with other data streams, security, cost, and technology configurability.

Figure 1. General Overview of Wireless Technology Categories

Quality of Service (QoS) requirements for medical data [Table 1] are defined in terms of reliability, latency, priority, and bandwidth. The ability of a wireless technology to provide necessary service to medical data in this context would define its QoS support. A variety of different medical devices exist within any given healthcare facility, with medical data streams having different levels of criticality. While some may be good candidates for wireless chip sets, others may perform better on conventional wired systems. This distinction may not be intuitively obvious to medical device and wireless manufacturers or end users without careful consideration of a complex set of variables. Several other considerations, namely increased benefits of mobility of both patients and healthcare staff, must also be considered. It is entirely possible that the added benefits outweigh certain reductions in QoS support.

Table 1. QoS requirements for different categories of medical device data

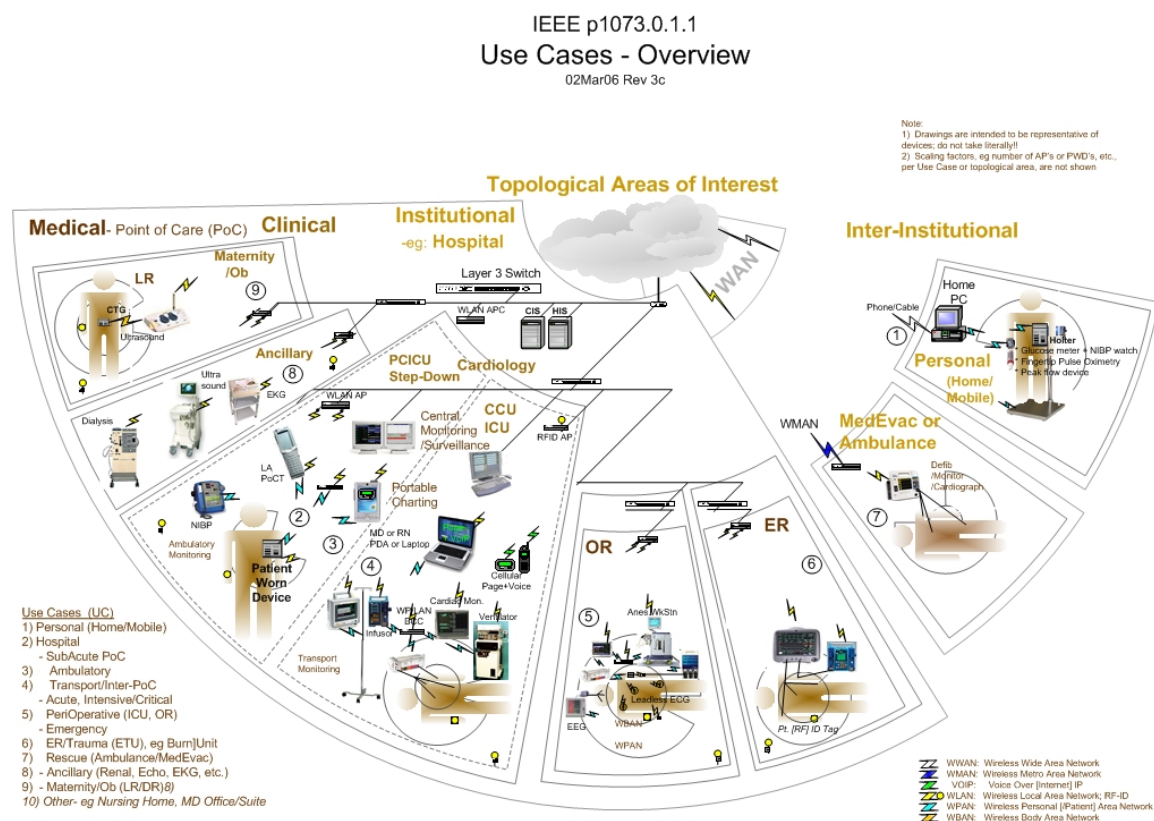

Data Type	Reliability	Latency	Priority	Bandwidth
Alarms / Alerts (Real-Time)	++++ [AAMI EC-13 - onset of asystole to alarm report]	< 250-500 ms [< 10 sec to central station; AAMI EC-13 - onset of asystole, bradycardia or tachycardia to alarm] < 3 s communication latency	++++	+ (64 bytes/alert) [intermittent]
Positional alert (Real-Time)	++++	< 3 s communication latency	++++	64 bytes /alert [intermittent] (data is per sensor)
Patient state change (Real-Time)	++++	< 3 s communication latency	++	64 bytes/ state change [intermittent] (data is per sensor)
Sensor watch dog / heartbeat	++++	< 1 min communication latency; ~ 1 time per hour	++	64 bytes/ state change [intermittent]
Reminder (Real-Time)	++++	< 3 s to receive from health care system	++	1632bytes/reminder [intermittent]
Waveforms (Real-Time)	+++	< 300 ms (e.g., during balloon pump in OR / ICU) < 3 s to central station < 7 s for telemetry to in-room monitor	+++	+++ [continuous] EEG: 120-4000+ bit/s (3-12 channels / minimal, monitoring, diagnostic) EEG: 120-250 bit/s (minimal, upper-end, BIS™) Ventilator: 50 - 60 bit/s SpO2: 50 – 120 bit/s
Video/Audio (Real-Time)	+++	< 300 ms	++	4Mbit/s (Bi-directional MPEG2 encoded 320X240 @30fps or 640X480 @30fps audio/video streams) 20Mbit/s (Bi-directional HDTV MPEG-4 video stream; 80kbit/s for VoIP)
Physiologic Parameters (Real-Time) [e.g., episodic bp, hr, SpO ₂ , ETCO ₂ , temp]	+++	< 10 s to central station < 3 s communication latency from nurse to clinician	+++	+ (20 bytes/param at 1/2 to 1 to 5 Hz) [episodic]
Non-Real-Time Parameters	+++	< 15 s time critical PoCT < 60 s otherwise (CLSI PoCT1-A) < 60 minutes for time-stamped, non time-critical items	++	600 bytes/measurement (CLSI PoCT1-A DML)
Non-Real-Time Events	+++	< 3 s in room < 5 s to central station	++	+ [intermittent]

OVERVIEW OF IEEE / ISO 11073 RF WIRELESS: POINT-OF-CARE MEDICAL DEVICE COMMUNICATION – TRANSPORT PROFILES – GUIDELINES FOR THE USE OF RF WIRELESS TECHNOLOGY

Control/Settings	+++	< 3 s in room < 5 s to central station	+++	+ [manual]
History / archive retrieval	++	< 5 s pushing < 5 s pulling	+	+++ [manual, bursty]
Web Browsing	++	< 5 s pushing < 5 s pulling	+	+++ [manual, bursty]

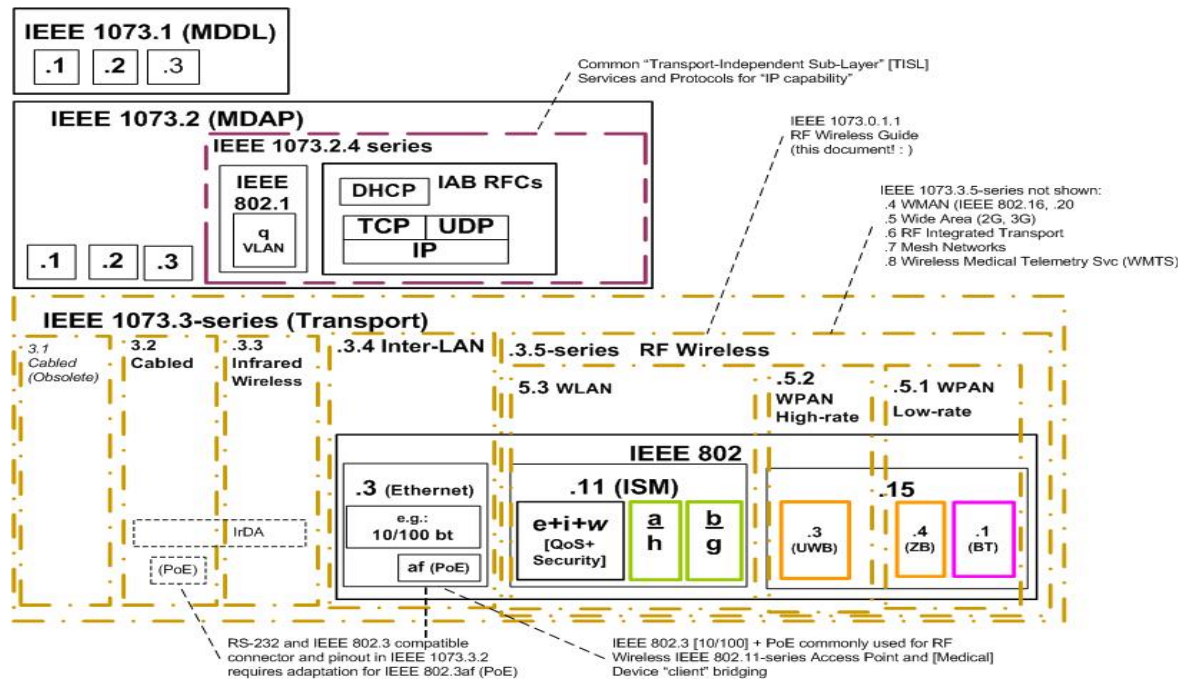

In order to address the use of wireless technology in healthcare, realistic use case scenarios have been developed to allow visual navigation of relevant issues involving QoS requirements and support [Figure 2]. These use cases represent a broad range of typical hospital-, home-, and mobile- healthcare scenarios ranging in degree of criticality and complexity.

Figure 2. Use case topological overview

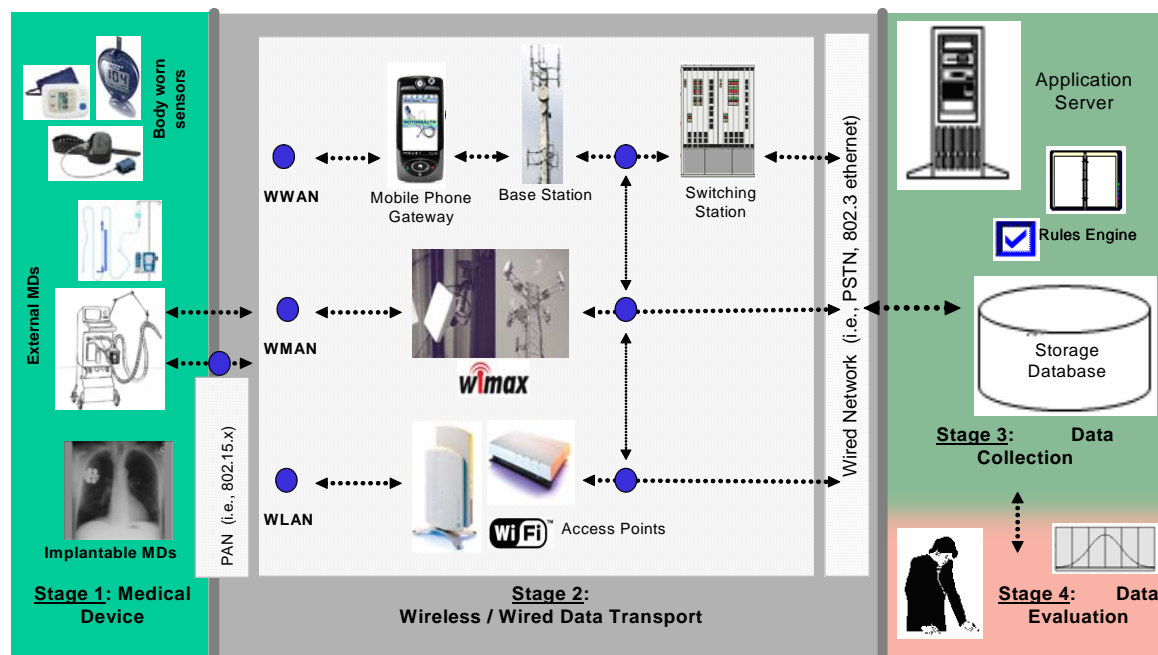

Medical data will often traverse several wireless links en route to the end server / healthcare professional, topological considerations that take different systems into account are necessary [Figure 3]. This example focuses on in-hospital IEEE 802.11 and IEEE 802.15 standards. Other hospital-, home-, or mobile-scenarios were not included to avoid complexity.

Figure 3. Topology Architecture

As medical devices become wirelessly enabled, the definition of a "medical device" becomes ambiguous. IEEE / ISO 11073 standards subdivide different stages of medical data transport [Figure 4] to offer some clarification for future assessment and regulation. Traditional definitions of the US-FDA [<http://www.fda.gov/cdrh/devadvice/312.html>] and UK-MHRA [<http://www.mhra.gov.uk/>] generally define MDs as products placed on market for patient health / safety that undergo regulatory approval (i.e., CE mark in the EU, FDA approval in the US) and do not address transport of information across wireless links or networks. In the broadest sense, a wireless MD might also include the host (e.g., data collection unit, server, nurse station) and the wireless links (e.g., IEEE 802.11x, IEEE 802.15.x, IEEE 802.16™, telecomm network, IEEE 802.3).

Figure 4. Stages of wireless medical devices

Summary: Proposed, ongoing, and completed IEEE / ISO 11073 RF Wireless Standards [Table 2] will offer guidance to healthcare providers, medical device manufacturers / vendors, wireless equipment manufacturers / vendors, and relevant agency groups for the use wireless technologies for medical data transport. It is a goal of this standards activity to define optimal wireless profiles and promote plug-and-play operability between commercially available medical devices and wireless systems. The effort primarily considers wireless technologies having physical layer protocols defined by industry standards (i.e., IEEE, ISO, ANSI, ITU-R, ITU-T). Compatibility between data exchange formats and upper layer protocols is also an objective to facilitate efficient plug-and-play interfacing and information exchange.

Table 2. IEEE / ISO 11073 RF Wireless family of standards (those in bold are actively in development)

IEEE Project	Scope	Purpose
IEEE P11073-10101	Nomenclature	numeric codes that identify items communicated between systems; partitioned code set that can be use din HL7 messages
IEEE P11073-10201	Domain Information Model (DIM)	Object oriented model: objects, attributes, and methods; all objects specified in ASN.1 notation
IEEE P11073-20000	Application profile – Framework and overview	Scope and purpose for application profile standards - sets and establishes structure for each of the component documents.
IEEE P11073-20400	Application profile – Network service - Framework and overview	Describes the role and types of network services contained within this subset, including their support of transport-specific technologies. This includes key capabilities such as: -Compatibility with IEEE 1073 transport profiles for WPAN, WLAN, WMAN, WWAN -Consistent with QoS outlined in IEEE 802.11e
IEEE P11073-20400	Application profile – Network service - Framework and overview	Describes the role and types of network services contained within this subset, including their support of transport-specific technologies. This includes key capabilities such as: -Consistent with QoS outlined in IEEE 802.11e -Compatibility with IEEE 1073 transport profiles for WPAN, WLAN, WMAN, WWAN
IEEE P11073-20401	Application profile – Network service - Directory	Find and bind services and systems on the network (e.g., a manager for a specific class of devices such as PoCT manager for manufacturer X's devices)
IEEE P11073-20402	Application profile – Network service – Quality of service (QoS) management	Provides a transport-neutral model for application level management of QoS capabilities. This includes detecting the QoS provided by an associated transport profile, as well as setting desired QoS parameters to be negotiated when a connection is established.
IEEE P11073-20403	Application profile – Network services - Location	Patient location, asset tracking, staff location and tracking [throughout supply chain (management) so not counterfeit, correct amount, etc.]
IEEE P11073-20404	Application profile – Network services - Identification	Patient ID, pharmacy ID, supply chain, RFID
IEEE P11073-20500	Application profile – Security – Framework and overview	Overview of issues and strategy for addressing security issues to support plug-and-play medical device communication; incl. security capabilities esp. to support patient demographics data communication ^a consistent / compatible with IEEE 802.11i and HL7 (1073.6.1.1)

IEEE P11073- 00101	Technical Report	Guidelines and foundation for RF wireless transport profiles
IEEE P11073- 30400	Transport profile – Internet protocol (IP) [based]	Profile the application of IP technologies for use in medical device communication, compatible with IEEE 1073-based Ethernet or WPAN, WLAN, wMAN, WWAN profiles, including vLAN, IP, medical session, QoS, security, UDP, TCP, multicast discovery, addressing characters, wired to wireless infrastructure, etc.
IEEE P11073- 30500	Transport profile – RF wireless – Framework and Overview	Presents the unique concerns and requirements relating to the use of RF wireless technologies for PoC medical device communication. Unique use cases addressed by RF wireless networks; links to guidelines doc 1073.0.0.1
IEEE P11073- 30501	Transport profile – RF wireless – Personal area networks (WPAN), Low-rate	Profile IEEE 802-series standards appropriate for low-rate PoC medical device data transport over short link distances (i.e., personal area networks). [802.15.1 ⁴ Bluetooth, 802.15.4 ⁴ ZigBee]
IEEE P11073- 30502	Transport profile – RF wireless – Personal area networks (WPAN), High-rate	Profile IEEE 802-series standards appropriate for high-rate PoC medical device data transport over short link distances (i.e., personal area networks); Ultra wide band (UWB) [802.15.3a ⁴]
IEEE P11073- 30503	Transport profile – RF wireless – Local area networks (WLAN)	Profile IEEE 802-series standards appropriate for high-rate PoC medical device data transport over in-building networks involving several patient areas (i.e., 802.11a⁴, 802.11b⁴, 802.11g⁴, 802.11n⁴ [data prioritization], 802.11i⁴ [encrypted transmission to improve security])
IEEE P11073- 30504	Transport profile – RF wireless – Metropolitan area networks (wMAN)	Profile IEEE 802-series standards appropriate for high-rate PoC medical device data transport over large regional areas (i.e., metropolitan area networks) / Broadband / certain UWB technologies
IEEE P11073- 30505	Transport profile – RF wireless – Wide area networks (WWAN)	Profile existing licensed telecommunication standards appropriate for PoC medical device data transport over large / regional distances (i.e., wide area networks) / mobile phones (2G [GSM, CDMA, iDEN] and 3G [UMTS, CDMA2000])
IEEE P11073- 30506	RF Integrated Transport[s]	Profile above standards for integrated (e.g., WLAN / WPAN, WPAN / WWAN) data communication
IEEE P11073- 30507	Transport profile – RF wireless – Mesh networks	Profile IEEE (802.11s ⁴ , 802.15.5 ⁴) standards appropriate for low to medium-rate PoC medical device data transport over large / regional distances operating via multiple node relays (i.e., mesh networks)
IEEE P11073- 30508	Transport profile – RF wireless – Wireless medical telemetry service (WMTS)	Profile future (IEEE 802-series, other) standards appropriate for PoC medical device data transport developed or modified for operation on WMTS bands

COUPLING TO SPECTACLE FRAMES FROM A 450 MHZ PERSONAL RADIO SOURCE OPERATING ANTERIORLY TO THE HEAD

The RF coupling potential of medium-power UHF personal radios operating in close proximity to wire framed spectacles was quantified in a scenario where the recommended minimum body-radio separation is not respected.

A custom and flexible FDTD simulator written in 'C' (COCA: Code for Coupled Antennas) was used for analysis, with a 2 mm atomically realistic adult head model truncated at the shoulders. The effects of radio orientation and spectacle shape (circular/square) on the polar pattern, induced current profile and SAR distribution was investigated. The undesirable effects of analysing tilted wire elements using the Yee algorithm were overcome by applying Dey-Mitra special update equations. The peak 1 g SAR was situated in the nasal bone region, due to localised parasitic-conductor contact at the bridge of the nose. This parameter was spectacle-shape dependent, as demonstrated by SAR values that were 70 % (rectangular frame) and 174 % (semi-rimless) greater than in the isolated (clean head) case of 3.98 W/kg, for a personal radio input power of 1 W. Partial eye screening occurred when both sets of conducting frames were in place. A maximum coupled current of 16 mA was computed in the semi-rimless frames.

Introduction

Personal radios, transmitting in the lower UHF range (435 MHz), have been identified as primary sources of interference when functioning in close proximity to body worn conductors (e.g. electronic sensing devices [1][2]). Similar effects can also be expected when a PR is operated close to the head, with the user wearing wire framed spectacles [3][4], whereby the minimum body-radio separation of 2.5 cm recommended by a range of manufacturers is not respected, thus placing the transmitting antenna very close to the face and eyes. This is of concern as the eyes are particularly sensitive organs due to their proximity to the surface of the head, their tendency to accumulate damage and cellular debris [5], as well as a limited ability to dissipate heat [6] due to relatively low levels of blood flow compared to other regions of the body.

To date, research into radiation effects in the presence of spectacles has been performed numerically for a cell-phone [7], Personal Digital Assistant applications [8][9], and by measurement [6][10]. The literature shows re-radiation effects [3] along with a rise in peak head SAR [3][8][9], in addition to frequency and spectacle-shape dependence of the average SAR in the eyes [8][9].

The objective of this work was to investigate the effects of a hand held 450 MHz radio fitted with a $\lambda/4$ monopole operated in front of the face (Figure 1a), with a self-developed FDTD program (COCA), by computing the antenna's input impedance, radiation pattern and SAR. These parameters were contrasted to the case when the PR user wore full wire-framed spectacles with rectangular lenses. Dey-Mitra's contour path model was implemented in COCA, enabling the typical practical scenario of a PR tilted by 45° (Figure 1b) to be scrutinised. Finally, COCA was employed to compute the currents induced in a semi-rimless spectacle frame fitted with circular lenses (Figure 1 c & d).

COUPLING TO SPECTACLE FRAMES FROM A 450 MHZ PERSONAL RADIO SOURCE OPERATING ANTERIORLY TO THE HEAD

Figure 1: Anterior-head radio / monopole system (vertical & tilted), with wrapped hand. In a) and b) the spectacle frame is 166 mm (0.241λ) wide, with 122 mm (0.177λ) legs and lens apertures 68 mm x 40 mm ($0.1 \lambda \times 0.06 \lambda$). Cases c) and d) have semi-rimless spectacles, with 152 mm (0.22λ) legs and a lens diameter of 68 mm.

Methodology

The FDTD computations were performed in a 2 mm grid, using the Brooks anatomically realistic phantom [11] truncated to the head and shoulders. The dielectric properties of the 21 distinct tissue types used (Table 2) were computed at 450 MHz, using a public domain computer program¹ based on published 4-Cole-Cole parameters [12]. The phantom was adapted by removing the normally closed eyelids, so as to leave the eyes exposed as in normal radio use and to investigate the worst-case scenario at the frequency of interest [8][9].

Figure 2: Horizontal section showing relative (rectangular lens) frame, antenna, radio and hand positioning.

The PEC box representing the handset was coated in a loss-less 2 mm insulating layer with $\epsilon_r = 2$. The $\lambda/4$ monopole, made from 2 mm diameter wire, was corner-located on the top surface of the radio, on the edge nearest the head (4 mm) to mimic worst-case operational conditions (Figure 2). The hand was modelled as a 4 mm core of bone surrounded by a 6 mm layer of muscle and a 2 mm coating of skin, covering all three sides of the handset. The antenna was initially length-adjusted for resonance in isolation, Table 1.

COUPLING TO SPECTACLE FRAMES FROM A 450 MHZ PERSONAL RADIO SOURCE OPERATING ANTERIORLY TO THE HEAD

The conducting spectacle frame consisted of 2 mm square-section PEC: this was positioned for normal wear, terminating behind the ears. Loss-less optical-glass lenses with $\epsilon_r = 7.75$ were fitted. The only body surface contact made by the frame was at the top of the nose and near the ears, with a separation of 2 mm (1 Yee cell) representing worst-case conditions.

Polar pattern alteration

At 450 MHz the human body acts primarily as a reflector; the low impedance presented to the wave by the body reduces the electric field nearby, whilst increasing the magnetic field. For antenna-body distances greater than $\lambda/4$ from the transmitter, a high impedance is presented to the approaching wavefront, which enhances the electric field at the same time as the magnetic field is reduced. At the far side of the body, away from the antenna, there is a deep null caused by power absorbed in tissue [13]. Because of the dominance of the magnetic field between the monopole and the frames, magnetic coupling occurs. This in turn causes an electric current to flow on the frames, which results in an increased electric field in their vicinity: the wire reradiates and the polar pattern changes.

In all cases studied, the radio is offset from the centre of the face. This results in asymmetric polar patterns as energy is absorbed in the head; see the deep null in Figure 3a). Both backward gains are enhanced by re-radiation from the spectacles: this effectively reduces null depths. The addition of either spectacle frame improves the forward gain and highlights the re-radiation due to induced currents. Tilting the handset has the effect of rotating the radiation pattern: Figure 3 b). Nulls appear both at the front and back of the head, but in the latter case are less pronounced than previously. The frontal null is created due to power absorbed in the nose. The increased forward gain was more noticeable with the square spectacles.

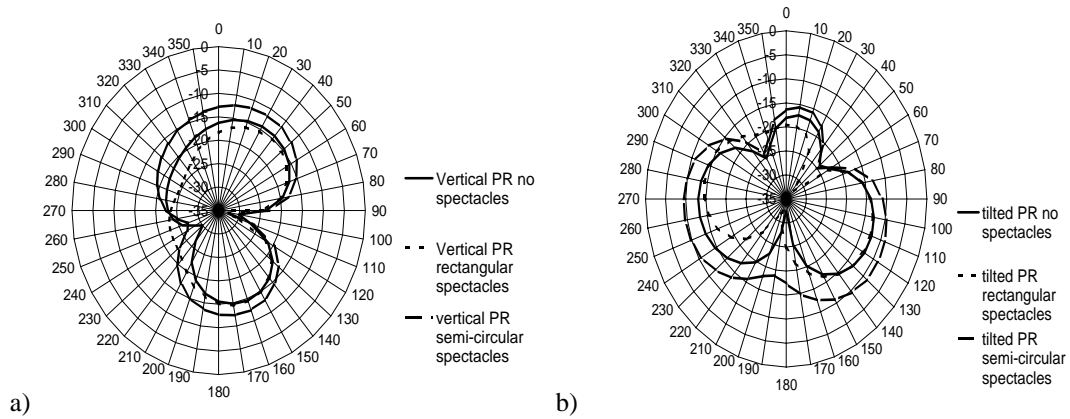

Figure 3: E_ϕ vertical far field patterns, with and without spectacles, for a) vertical and b) tilted personal radios.

Vertical PR SAR results

Computed SAR values were all scaled for an antenna input power of 1 W, and are summarised in Table 3. When the radio is beside the ‘clean’ phantom head there is detuning: the input resistance falls to 66.1Ω and the reactance becomes capacitive, at $-j0.72 \Omega$. With spectacles, the input resistance decreases further to 65.4Ω , and the reactance becomes inductive.

Table 3: Computed input impedance and peak SAR in the head and eyes in the cases of a vertical and tilted PR proximal to the head. SAR levels were normalised against 1 W transmitter output power.

	Vertical PR			Tilted PR		
	Without spectacles	With rectangular lenses	With semi-rimless lenses	Without spectacles	With rectangular lenses	With semi-rimless circular lenses
Input impedance (Ω)	66.1-j0.72	65.4+j1.4	64.36-j0.7	68.73-j9.41	68.94-j6.4	72.82+j8.83
Peak head SAR (W/kg)						
1-g	3.98	6.77	10.89	3.31	8.53	5.38
10-g	2.65	2.75	2.89	2.14	2.41	2.22
1-g peak eye SAR (W/kg)						
Right	1.16	0.7	0.79	0.23	0.14	0.22
Left	0.35	0.31	0.35	1.01	0.51	1.08

Figure 4 shows the SAR profiles in the relevant vertical head sections, with 0 dB corresponding to maximum power dissipation in each case. For 1 g mass averaged SAR, the displacement of the hotspot in each instance is evident. Without spectacles the maximum SAR in the head was 3.98 W/kg; this occurred in the muscle (*orbicularis oris*) between the oral and nasal cavities, at a tissue depth of 12 mm and in a vertical plane displaced 4 mm towards the antenna from the head's midline axis. With the rectangular-framed spectacles, energy absorption is more spread out over the nose, with a peak 1 g SAR of 6.77 W/kg (a rise of 70 %), in the nasal bone region (*nasalis*) at 4 mm deep in the midline plane, due to localised parasitic-conductor contact at the bridge of the nose. In [8] and [9], it is reported that SAR is dependent on the shape and size of the wearer's spectacles. Similarly here, the SAR with semi-rimless spectacles is concentrated at the upper and lower extremities of the nose, rising to 10.89 W/kg, an increase of 174 % and 61 % compared to the isolated and rectangular-framed cases, respectively. Unsurprisingly, for a higher averaging tissue mass of 10 g, the peak SAR without spectacles was lower at 2.65 W/kg. Increases still occurred in the nasal region (though not as significant), up 3.77 % to 2.75 W/kg with the rectangular frames, and 9.1% to 2.89 W/kg with the semi-circular. The human head is a complex, highly detailed organ; indeed the human eye or pinna/external ear have masses of as little as 10 g [14]. Furthermore, certain cells or neurons in the brain can be misrepresented by 1 g of tissue [14]. An 8 mm³ Yee grid is employed here, which could explain the relatively high 1 g semi-circular spectacle SAR result. This suggests that the peak 1 g SAR is associated with a single hot-spot rather than a general increase in SAR values within the user's head.

COUPLING TO SPECTACLE FRAMES FROM A 450 MHZ PERSONAL RADIO SOURCE OPERATING ANTERIORLY TO THE HEAD

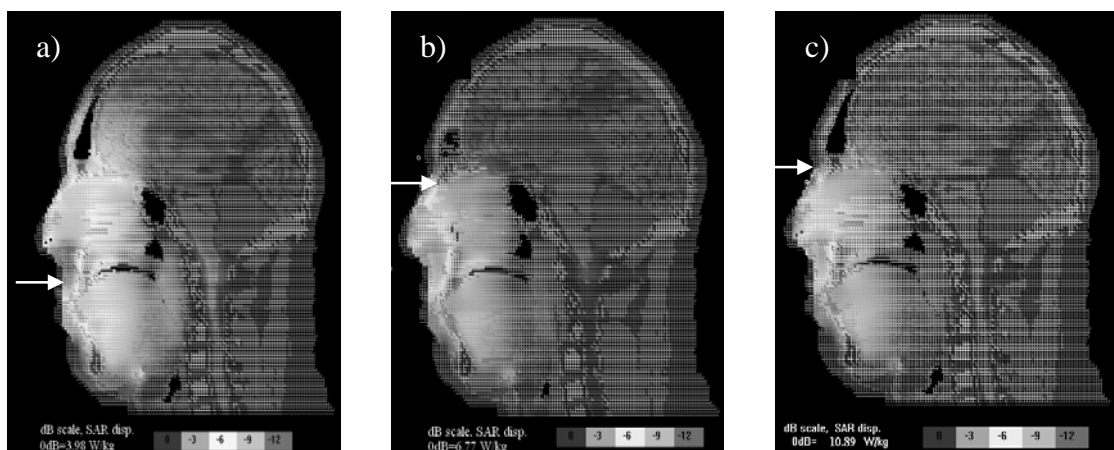

Figure 4: 1 g mass averaged SAR for a vertically-oriented PR beside head a) clean b) with rectangular-framed spectacles and c) with semi-circular frames.

Eye SARs were computed to establish conditions in this particularly sensitive body tissue. With the antenna passing 30 mm from the right eye, and without spectacles, the 1-g peak SAR was 1.16 W/kg. For the left eye, 80 mm from the antenna, the corresponding value was more than 70 % lower (0.35 W/kg). Partial eye screening occurred when both sets of conducting frames were in place; the 1-g SAR fell by 40 % in the right eye and 11.4 % in the left with the rectangular frames in use, as noted in Table 3. A similar phenomenon occurred with the semi-circular frames, with a 32 % SAR reduction in the right eye and an unchanged SAR in the left. All reported SARs were computed for a CW excitation, which implies that they would be further reduced if realistic TDMA duty cycles were taken into account: consequently, they are well within the IEEE guidelines for occupational users. SAR is, however, proportional to the antenna input power, which implies that if transmitter output level rises (a current trend in PR design as hardware improves) then safety limits are likely to be exceeded.

Tilted PR SAR results

Here, the PR was tilted by 45°, as illustrated in Figure 1b. Rotating the radio caused the free space input resistance to decrease by 4.12 %. However, turning the handset had a more noticeable effect on the input reactance, as it became more capacitive - see Table 3.

Placing the spectacles on the phantom caused both the input resistance and reactance to increase positively. Inclination of the radio caused the frame-free 1 and 10 g SARs to be 17 % and 19 % lower than in the vertical PR case, respectively, at 3.31 and 2.14 W/kg. The peak 1g SAR in the eye was situated close to the monopole's feedpoint, in the left eye (1.01 W/kg). Both peak eye SARs without spectacles were less than, or equal to, those with frames and the vertical radio. The 1 g mass averaged SAR profiles with and without spectacles are presented in Figure 5.

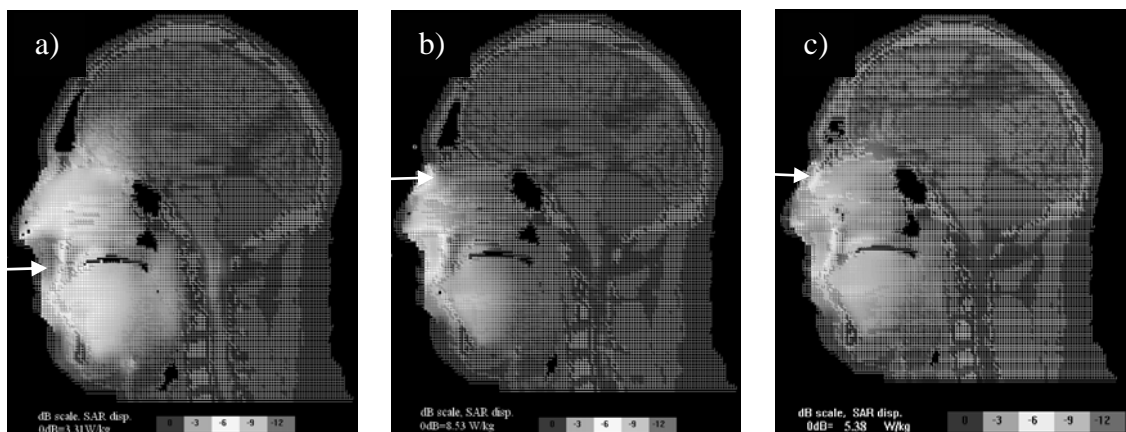

Figure 5: 1 g mass averaged SAR for a tilted PR close to head a) 'clean' b) with a rectangular frame and c) with semi-rimless circular lenses.

As with the vertical PR, the SAR hotspot without spectacles is situated between the oral and nasal cavities. With rectangular-framed spectacles, a second very distinctive concentration is generated at the top of the nasal bone region. There is less SAR 'spread' than in the corresponding vertical PR case (Figure 5b). For semi-circular frames, substantial SAR spreading is again evident.

With the rectangular frames the eyes were partially screened, as substantiated by the 50% reduction of the SAR in the eye nearest the antenna, and 39 % decrease in the other. However, only marginal changes occurred in the case of the semi-circular frames: SAR in the left eye increased by 7 % and decreased in the right by 4 %.

Induced currents

The induced current distribution on spectacle frames has previously been investigated at 1.5 GHz in [7], with a mobile telephone radiating 1 W close to the ear of an anatomically based head model. Two different types of spectacle frames were studied - one with rims and legs both metallic, and the other rimless, with metallic legs only. Current profile discontinuities were present in this model, where the nosepiece intersected each lens' outer contour and at the intersection of the metallic leg and outer rim. The discussion on circular frames has a number of similarities with electrically small loop antennas, which are equivalent to infinitesimal magnetic dipoles; the current distribution in loops of perimeter less than 0.3λ is taken to be constant around the loop [16].

Computing induced current in a pair of spectacles is challenging in terms of EM simulation, as this creates a number of discontinuities. Because of this, the simulations here were done in two stages. Firstly, a 'flat' spectacle model was assembled (Figure 6a), after which the legs were bent, as depicted in Figure 6b.

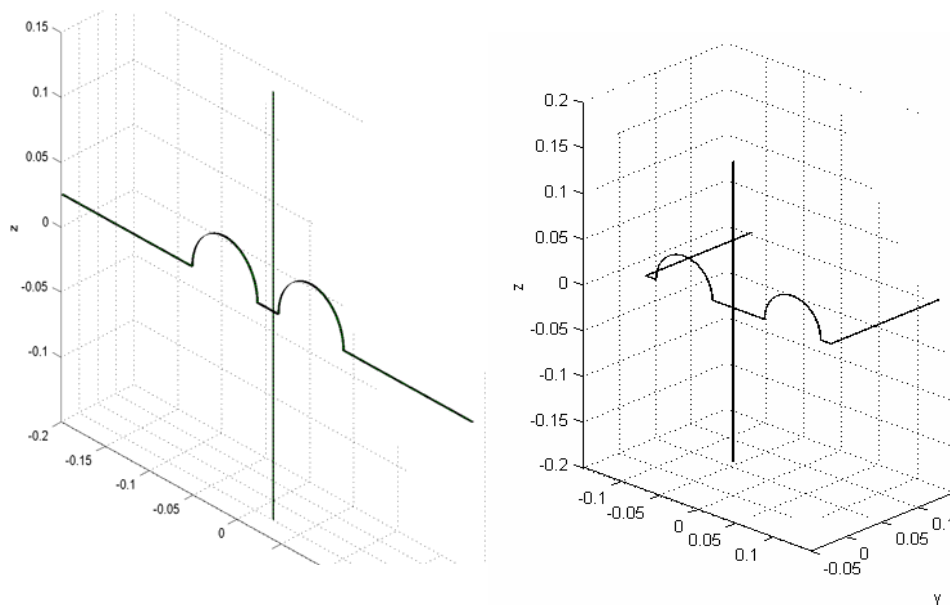

Figure 6: Dipole coupled to a) flat spectacle frame b) a spectacle frame with bent legs; in b) $Z_{in} = 64.4 - j9.2 \Omega$.

This done, the induced currents were computed with COCA, as illustrated in Figure 7.

COUPLING TO SPECTACLE FRAMES FROM A 450 MHz PERSONAL RADIO SOURCE OPERATING ANTERIORLY TO THE HEAD

Figure 7: Induced current in the top section of half-rim wire frames adjacent to a 450 MHz dipole ($P_{in} = 0.32$ W).

The spectacles coupled to the dipole have an overall length of 0.6λ : two pseudo standing waves are generated that reach minima at the outer extremities of the spectacle legs and at the middle of the nosepiece. Two small reflections at both nosepiece extremities (T junction) emerge, with current maxima of 4 mA at the top of each loop. Bending the legs by 90° causes the induced current to decrease overall. The currents computed are significant, reinforcing the source of the increased forward gains obtained.

Finally, the result of introducing the phantom head was investigated. The PR monopole was corner-located on the handset chassis and held to the right of the user's nose, as illustrated in Figure 2, causing the radiating antenna and case to be strongly coupled to the adjacent semi-circular lens. On this basis, the left lens was shadowed by the nose. This gave a smoother, full standing wave (Figure 8), with current maxima of 16 and 11 mA. The increased current magnitude is because of less detuning in this case, plus the majority of the energy radiated by the monopole is above the PR's 'groundplane'.

Figure 8: Induced current on semi-circular spectacles with 90° legs, coupled to a vertical 450 MHz monopole / case close to an anatomically realistic head ($P_{in} = 0.32$ W).

Conclusions

The coupling between a personal radio handset and the human head was investigated at 450 MHz, for two realistic radio orientations, vertical and tilted by 45°. For each orientation, a spectacle-free phantom was contrasted to a model wearing rectangular and semi-circular frames. In each simulation the polar pattern, SAR distribution and induced current profiles were computed.

Absorbed power levels were dependent on the PR's orientation and on the shape of the wire spectacle frames, as evidenced by a 1g SAR ranging between 3.31 and 10.89 W/kg. In the instance of the vertical PR, partial eye screening occurred when both sets of conducting frames were in place. This was only the case with the rectangular frames when the PR was tilted. In general, frame-conductor re-radiation enhances polar pattern forward gain and reduces backward-facing nulls.

Magnetic coupling between the PR and the semi-circular frames caused a cosine-like standing-wave to be developed on the frames, with unequal maxima on the right and left semi-circular loops because of obstructive tissue absorption.

Abstract

This paper presents the computational electromagnetic field (EMF) dosimetry inside a woman-torso model, which is exposed to E- and H-polarised waves, in the first gestational month using the finite-difference time-domain (FDTD) method over the frequency range from 10 MHz to 3 GHz. First, parametric models for the dielectric spectrum of fetus and those of amniotic fluid are demonstrated. Second, the whole-body average SAR in the embryo is calculated, when the incident power density of plane waves is ICNIRP or IEEE occupational reference level. As a result, the maximum value is less than 0.4 W/kg (occupational limit) over the frequency range from 10 MHz to 3 GHz. Finally, the internal SAR distributions inside the torso model are also shown at 10 MHz, 100 MHz, and 1 GHz. As a result, the SAR distribution around the embryo is dependent on the frequency and polarized wave in the first gestational month.

1. Introduction

Today many devices emitting EMFs are widely used in the close vicinity of the human body. Consequently, the evaluation of the specific absorption rate (SAR) in various models, such as adults, children, and pregnant women and their fetuses is necessary. Especially the priority on EMF dosimetry in embryos and fetuses is growing [1]. In the early term of pregnancy, it could be possible that the embryos are exposed to EMFs when mothers do not know their pregnancy yet. Therefore, EMF dosimetry in the embryos is important.

Until now, Fleming and Joyner [2] have proposed the EMF dosimetry inside the embryo in 80-100 MHz and fetus across the range 300-1500 MHz, when the pregnant women are exposed to plane wave. In addition, Dimbylow [3] have presented the EMF dosimetry inside a whole-body pregnant woman and her developing fetus in 8-, 13-, 26- and 38-weeks of gestation at 50 MHz. However, the dosimetry inside the embryo over the wide frequency range have not minutely evaluated yet.

Hence, this paper presents the computational EMF dosimetry inside a woman-torso model, which is composed by five types of tissues, in the first gestational month, when the model is exposed to E- and H-polarised waves. Here, the EMF is calculated using the FDTD method [4] over the frequency range from 10 MHz to 3 GHz. Furthermore, the incident power density of plane waves is the international EMF reference levels (ICNIRP [5], IEEE [6], and occupational limit) in each frequency. Moreover, the internal SAR distributions inside the torso model are also calculated at 10 MHz, 100 MHz, and 1 GHz.

2. Models and method

2.1 Dielectric properties of embryo

The dielectric properties of biological tissues are very important parameters for the EMF dosimetry. Gabriel [7] has proposed parametric models for the dielectric spectrum of various types of tissues using the summation of 4-Cole-Cole equation. The dielectric properties at the target frequency are given by the following equation [7].

$$\hat{\epsilon}(\omega) = \epsilon_{\infty} + \sum_{n=1}^4 \frac{\Delta\epsilon_n}{1 + (j\omega\tau_n)^{1-\alpha_n}} + \frac{\sigma_i}{j\omega\epsilon_0} \quad (1)$$

where ϵ_{∞} is the material permittivity at terahertz frequency, ϵ_0 is the free-space permittivity, σ_i is the ionic conductivity, and $\Delta\epsilon_n$, τ_n , α_n are material parameters for each dispersion region. However, parametric models of expectant tissues, which are the amniotic fluid, placenta, and fetus (embryo), have not proposed yet in [7].

In fetal tissues, substituted dielectric properties from adult tissues using the variation in the water content [8] are usually used [3]. In addition, the properties of placenta are about the same values of blood, because the composition of the two is about the same. Moreover, Luca *et al* [9] have proposed the parametric model of the conductivity of amniotic fluid over the frequency from 1 MHz to 1 GHz.

Ito *et al* [10] have demonstrated the measured dielectric properties of fetus of rabbit and those of amniotic fluid of human over the frequency range from 100 MHz to 3 GHz. However, their results cannot apply to the other frequency. Therefore, we present the parametric models using the Eq. (1), to expand the wide frequency range. Table 1 describes the parameters of amniotic fluid and those of fetus for the Eq. (1). These parameters are defined using the simplex method based on the differences between the estimated properties by Eq. (1) and measured values as shown in Fig. 1. The parameters can realize the minimization of the difference between the estimated and measured values. In this paper, the dielectric properties based on the parameters in Table 1 are used from 10 MHz to 3 GHz.

Table 1 Parameters of amniotic fluid and those of fetus for the Cole-Cole equation

Tissue	ϵ_{∞}	$\Delta\epsilon_1$	τ_1 [ps]	α_1	$\Delta\epsilon_2$	τ_2 [ns]	α_2	$\Delta\epsilon_3$	τ_3 [μ s]	α_3	σ_i
A_fluid	4	75	7.23	0.14							1.42
Fetus	4	57	8.38	0.10	6000	133	0.1	1.20E+06	318	0.10	0.12

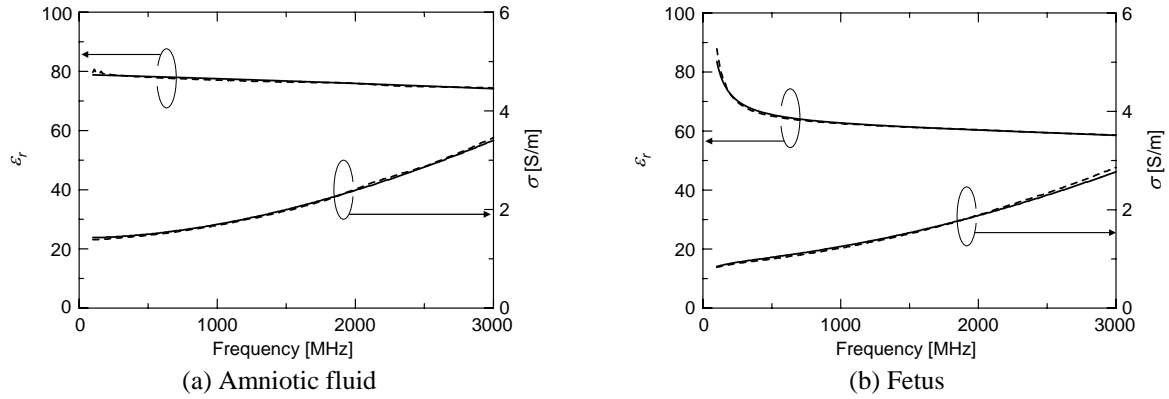

Fig. 1 Graphic representation of dielectric properties of amniotic fluid and fetus using Eq. (1) and Table 1 (line) together with the measured data (dotted line) [10].

2.2 Numerical model

Figure 2 shows a woman-torso model in the first gestational month. This model was scaled down from a woman-torso model in the 35th gestational week based on the external shape and magnetic resonance (MR) images [11]. The model was segmented seven different types of tissues, which were body, bone, bladder, uterus, embryo, placenta, and amniotic fluid. However, in the first gestational month, the amniotic fluid and placenta have not generated yet. Hence, we substituted the dielectric properties of uterus for the values of the two.

Fig. 2 Torso model of woman in the first gestational month.

2.3 Numerical condition

The FDTD software (X-FDTD ver. 6.3.8.3, by Remcom Engineering AG, PA, USA) was used for the EMF calculating inside the torso model. The parameters of FDTD calculation employed in this paper were as follows. The cell size was 2.5 mm. The numerical region was $190 \times 150 \times 413$ cells ($475 \times 375 \times 1032.5$ mm³). In addition, the absorbing boundary condition was the perfectly matched layer (PML) (eight layers).

Dielectric properties of the tissues, which were excluding the fetus, were based on the parametric models in [7]. Here, the properties of body was the 2/3 those of muscle. The incident waves were E- (E_z applied) and H-polarized (E_y applied) waves propagating from the front to the back of the model. The incident power density was from 1 to 5 mW/cm² (ICNIRP) or 1 to 10 mW/cm² (IEEE), which were the reference levels for occupational exposure to EMFs over the frequency range from 10 MHz to 3 GHz [5], [6].

3. Results

3.1 Whole-body average SAR

Figure 3 (a) and 3 (b) show the calculated results of the whole-body average SAR in the embryo over the frequency range from 10 MHz to 3 GHz, when the incident power density is ICNIRP or IEEE occupational level, which is dependent on the frequency. From Figs. 3 (a) and 3 (b), the SARs by E- and H-polarized waves are less than 0.4 W/kg (occupational limit) from 10 MHz to 3 GHz in both incident levels. In addition, the maximum value by the H-polarized wave is lower than that by the E-polarized wave in the estimated frequency range.

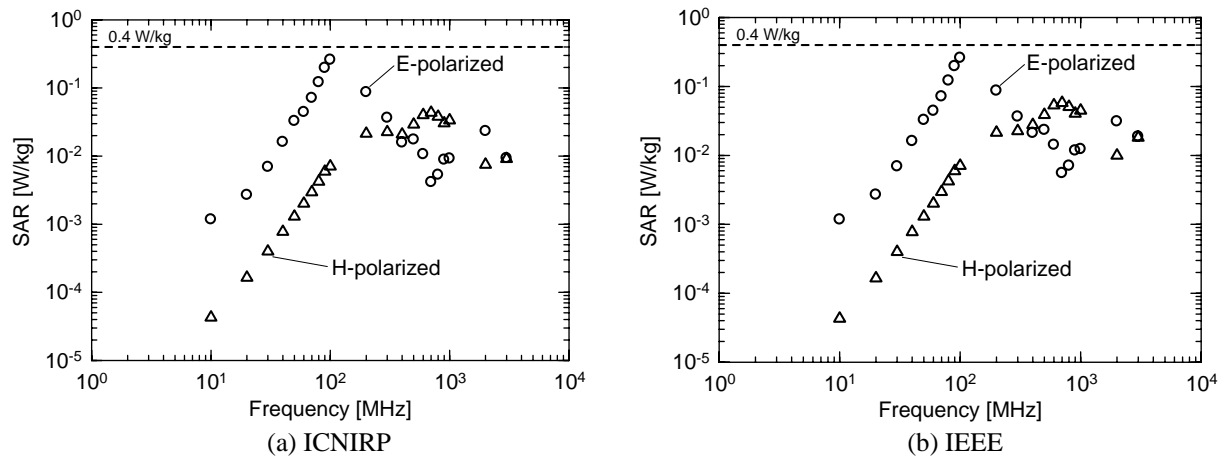

Fig. 3 Whole-body average SAR inside the embryo by the plane waves' exposure (circle: E-polarized wave and triangle: H-polarized wave).

3.2 SAR distribution

Figure 4 (a) and 4 (b) illustrate internal SAR distributions on the observational line [see Fig. 4 (lef)] in the median plane of the torso model by the E- or H-polarized wave's exposure at 10 MHz, 100 MHz, and 1 GHz. Here, the incident power density was IEEE occupational reference level in each frequency.

From Fig. 4 (a), the attenuation curve of SAR by the E-polarized wave at 10 MHz is almost equal to that at 100 MHz while the absolute value is significantly different. At these frequencies, in addition, the SAR distribution is almost constant between the uterus and the embryo and higher than the SAR in the frontal body. On the contrary, the attenuation is abruptly varied by the standing wave at 1 GHz.

As shown in Fig. 4 (b), the attenuation curve of SAR by the H-polarized wave in each frequency is about the same. In addition, the peak SAR is arisen on the surface in each frequency. Moreover, the SAR in the embryo and that in the uterus are about the same.

From Fig. 4 (a) and (b), the SAR in the embryo is almost continually varied between the uterus and the embryo in each frequency and incident wave, because the embryo is very small in the first gestational month. These results suggest that the layered structure between the uterus and embryo is not necessary to evaluate the SAR inside the embryo in the first gestational month.

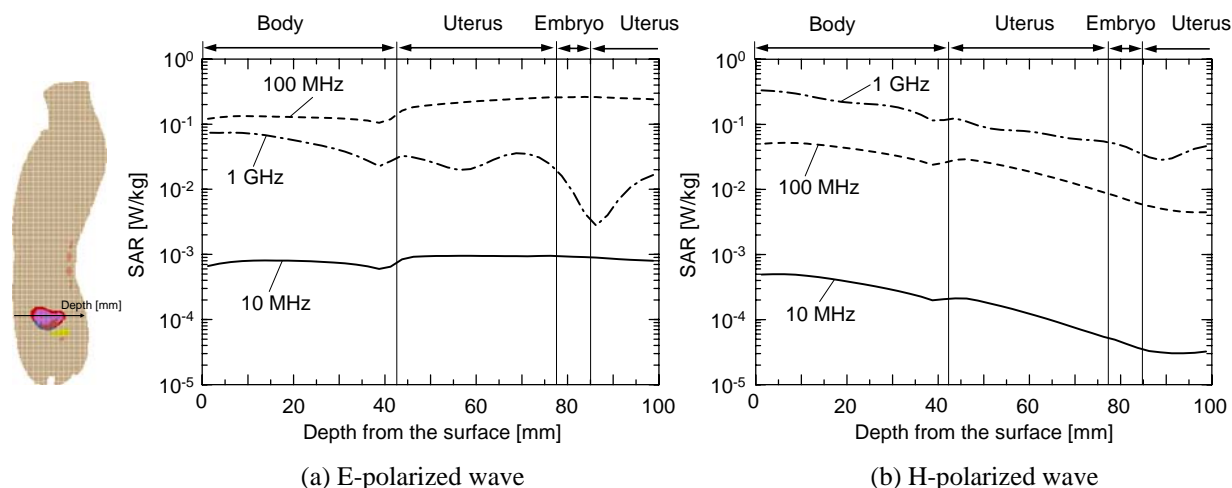

Fig. 4 Internal SAR distributions on the observational line in the median plane of the torso model by the plane wave's exposure at 10 MHz (line), 100 MHz (dotted line), and 1 GHz (dashed-dotted line).

4. Conclusion

This paper presented the computational EMF dosimetry inside the woman-torso model, which was composed by five types of tissues, in the first gestational month using the FDTD method, when the model was exposed to the E- and H-polarized plane waves over the frequency range from 10 MHz to 3 GHz. First, the parametric models for the dielectric spectrum of fetus and those of amniotic fluid were demonstrated. Second, the whole-body average SAR inside the embryo was calculated, when the incident power density of plane waves was ICNIRP or IEEE occupational reference level. As a result, the maximum value in the embryo was less than 0.4 W/kg (occupational limit) by plane waves' exposure over the evaluated frequency range. Finally, the internal SAR distributions inside the torso model were also shown at 10 MHz, 100 MHz, and 1 GHz. As a result, the SAR distribution around the embryo was dependent on the frequency and polarized wave in the first gestational month.

As a further study, the same investigation as above will be done using pregnant and non-pregnant women models, which is segmented much different tissues.

ELECTROMAGNETIC POWER ABSORPTION IN CURVED BIOLOGICAL TISSUES

A. SHTROM, D. F. SOLDEA, and P. D. EINZIGER

DEPARTMENT OF ELECTRICAL ENGINEERING,
TECHNION - ISRAEL INSTITUTE OF TECHNOLOGY, HAIFA 32000, ISRAEL

Abstract

Coupled closely to highly absorbing tissues, a source of electromagnetic radiation, such as cellular or hyperthermia antenna, can be greatly affected by the curvature of the absorbing surface. Herein, our previous TE excitation models are extended as to incorporate the TM case, combining an effective and relatively simple procedure for obtaining closed-form corrections for the main power relations involved in the presence of curved-surface absorbing tissues. The derivation is introduced by considering two-dimensional prototype models of surface and line magnetic-type sources radiating in the presence of a half-space and an infinite circular cylinder. The power absorption efficiencies of the cylindrical model are shown to be tightly bounded, both from below and above, by those of the half-space (planar) models.

Introduction

Recently, the study of near-field interactions of electromagnetic sources with highly lossy media, utilizing the Leontovich surface impedance approach [1], [2], has led to analytic readily-interpretable expressions for the main power relations involved in such configurations, namely, source power efficiencies and specific absorption rate [3],[4],[5]. These models, corresponding to a semi-infinite absorbing medium in the vicinity of either finite (current line-source) or infinite (planar current-sheet) sources, lead to an explicit dependence of the power relations on both the geometrical and physical parameters and provided an effective mean for obtaining physical insight into the basic power absorption mechanisms as well as tight bounds and estimates on the power relations. In some realistic configurations, however, such as cellular phone interaction with living tissues [6], [7], electromagnetic hyperthermia-based treatments [8], [9], and highly-sensitive biosensing [10], [11], the absorbing structure's curvature effect should be incorporated into the model in order to render its implementation effective.

Herein, our previous TE excitation models [12] are extended as to incorporate the TM case, utilizing the Leontovich surface impedance approach [1], [2], applied for finite-size two-dimensional (2D) cylindrical absorbing medium. The resultant extension leads to a discrete Parseval's representation for the power relations in terms of the individual cylindrical harmonics' (spectral) power content. These expressions can be interpreted similarly as for the previous (planar) case but with a curvature correction term, continuously depending on the effective surface curvature and the source location. Inclusion of the curvature correction, whenever applicable, enables thereby better understanding and design of prototype systems involving electromagnetic sources closely coupled to highly lossy structures.

Methods

The 2D physical configurations, corresponding to the planar and the cylindrical models, are depicted in Figs. 1(a), 1(b) and Figs. 1(c), 1(d), respectively. Both configurations are characterized by the parameters μ , ε , and σ via: $k_0 = \omega\sqrt{\mu_0\varepsilon_0}$, $Z_0 = \omega\mu_0/k_0 = \sqrt{\mu_0/\varepsilon_0}$, $\sigma_0 = 0$, and $k_1 = \omega\sqrt{\mu_1\tilde{\varepsilon}_1}$, $Z_1 = \omega\mu_1/k_1 = \sqrt{\mu_1/\tilde{\varepsilon}_1}$, $\tilde{\varepsilon}_1 = \varepsilon_1(1 - j\sigma_1/\omega\varepsilon_1)$ where, assuming a harmonic time-dependence $e^{j\omega t}$, $\Im\{k_1\} \leq 0$, and $\Im\{Z_1\} \geq 0$. The analysis and the results for the planar model are well known [2],[3],[4], and thus, summarized herein merely for the sake of comparison, completeness, and clarity. The excitation source locations for both models are given via $y' = d$ (the planar model) and $\rho' = a + d$ (the cylindrical model), where a and d denote the cylinder radius and the sources distance from the lossy tissues, respectively. Additionally, for line sources, $x' = 0$ (the planar model) and $\varphi' = 0$ (the cylindrical model).

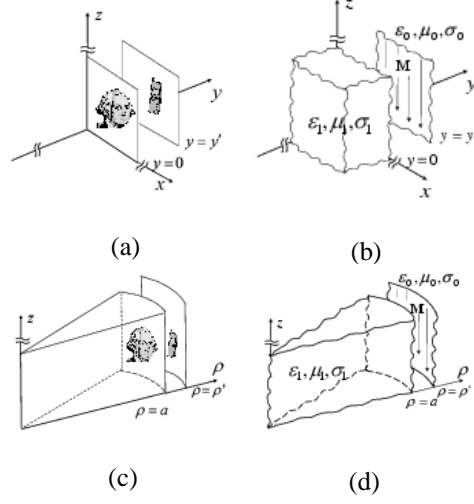

Figure 1: Physical configurations and models for the planar and the cylindrical approaches: (a) Physical configuration, (b) Planar model, (c) Physical configuration incorporating curvature correction, (d) Cylindrical model.

Source representations in terms of surface and line magnetic currents are denoted by $\mathbf{M}^S = -M^S \hat{\mathbf{z}}$ and $\mathbf{M}^L = -M^L \hat{\mathbf{z}}$ respectively, and given in Table 1.

Table 1: Magnetic current sources.

Current source	Planar model	Cylindrical model
M^S	$Ke^{jk_x x} \delta(y - y')$	$I \frac{e^{jq\varphi} \delta(\rho - \rho')}{2\pi\rho'}$
M^L	$I\delta(x)\delta(y - y')$	$I \frac{\delta(\varphi)\delta(\rho - \rho')}{\rho'}$

The power relations for both models, including radiation power, absorption power, source power, free space source power, power absorption efficiency, and power radiation efficiency, are given via

$$P_{r,P_C} = \mp \frac{1}{2} \Re \left\{ \int E_x H_z^* ds \Big|_{y_{\rho}^{\pm}} \right\}, \quad (1)$$

$$P_{a,P_C} = \pm \frac{1}{2} \Re \left\{ \int E_x H_z^* ds \Big|_{y_{\rho}^{\pm}} \right\}, \quad (2)$$

$$P_s = P_r + P_a, \quad (3)$$

$$P = P_s|_{\varepsilon_1=\varepsilon_0, \sigma_1=0}, \quad (4)$$

$$\eta_a = \frac{P_a}{P_s}, \quad (5)$$

and

$$\eta_r = \frac{P_r}{P_s} = 1 - \eta_a, \quad (6)$$

respectively. Note that the distinguishing superscripts S and L (Table 1) and subscripts P and C (Eqs. (1)-(2)), corresponding to the surface and the line currents and to the planar and the cylindrical models, respectively, have been omitted in Eqs. (3)-(6) since these equations apply to both current sources and models. This rule is adapted throughout the entire paper for all the equations that apply to both current sources and models. The fundamental power relations in Eqs. (1)-(4) can be readily expressed in the spectral domain upon expanding the transverse components of the electromagnetic field in terms of appropriate modes in conjunction with the Parseval's identity, as summarized in Table 2. The modal fields are represented via plane-waves (continuous spectrum) and cylindrical waves (discrete spectrum) for the planar and the cylindrical models, respectively. The spectral power densities, denoted by P_r , P_a , and P_s in Table 2, are expressed explicitly in Table 3.

Table 2: Spectral representation for the power relations.

Results

The limit of high losses, associated with highly lossy tissues, renders $|Z_1/Z_0| \rightarrow 0$ (or equivalently $|k_1/k_0| \rightarrow 0$) and thus enables the implementation of the well known Leontovich surface impedance approach [1], [2]. This results in a closed-form and relatively simple asymptotic relations for both the planar and the cylindrical models, as summarized in Table 4. These asymptotic relations demonstrate that utilizing the Leontovich approximation [1], [2] in conjunction with the Debye approximation [13] results in an asymptotic equivalence of the planar and the cylindrical models, when excited by surface currents.

Table 4: The limit of high losses.

Asymptotic limits	Planar model	Cylindrical model
Leontovich approx. [1],[2] $\left \frac{k_1}{k_0}\right \rightarrow \infty$ or $\left \frac{k_1 a}{k_0 a}\right \rightarrow \infty$	$\mathcal{Z}(k_x) \sim \frac{Z_1}{Z_0} \frac{k_0}{\beta_0(k_x)}$ $\Gamma(k_x) \sim 1 - 2 \frac{Z_1}{Z_0} \frac{k_0}{\beta_0(k_x)}$ $\left. \frac{E_x(k_x)}{H_z(k_x)} \right _{y=0} \sim Z_1$	$\mathcal{Z}_q \sim \frac{Z_1}{Z_0}$ $\Gamma_q \sim \left[1 - 2 \frac{Z_1}{Z_0} \Re\{w_q\} \right] \frac{w_q^*}{w_q}$ $\left. \frac{E_{\varphi,q}}{H_{z,q}} \right _{\rho=a} \sim -Z_1$
Leontovich approx. [1],[2] & Debye approx. [13] $q = k_0 a \sin \theta_q \rightarrow \infty, \sin \theta_q \neq 1$	$\mathcal{Z}(k_0 \sin \theta_q) \sim \mathcal{Z}_q w_q$ $\Gamma(k_0 \sin \theta_q) \sim \Gamma_q$	$\frac{H_q^{(1)'}(k_0 a)}{H_q^{(2)'}(k_0 a)} \sim \pm j \frac{\sqrt{(k_0 a)^2 - q^2}}{k_0 a} = \pm j \cos \theta_q$ $H_q^{(1)}(k_0 a)$ $w_q \sim 1/\cos \theta_q$

Furthermore, this equivalence establishes an identical asymptotic lower bound on the power absorption efficiency η_a^S in (5) for the planar and cylindrical waves in both models, as demonstrated in Fig. 2, i.e.

$$\eta_a^S \geq \eta_a^S \Big|_{\substack{k_x=0 \\ k_0}} \text{ or } \frac{q}{k_0 a} = 0, \quad (7)$$

in the range, $0 \leq k_0 d < \frac{\pi}{4}$.

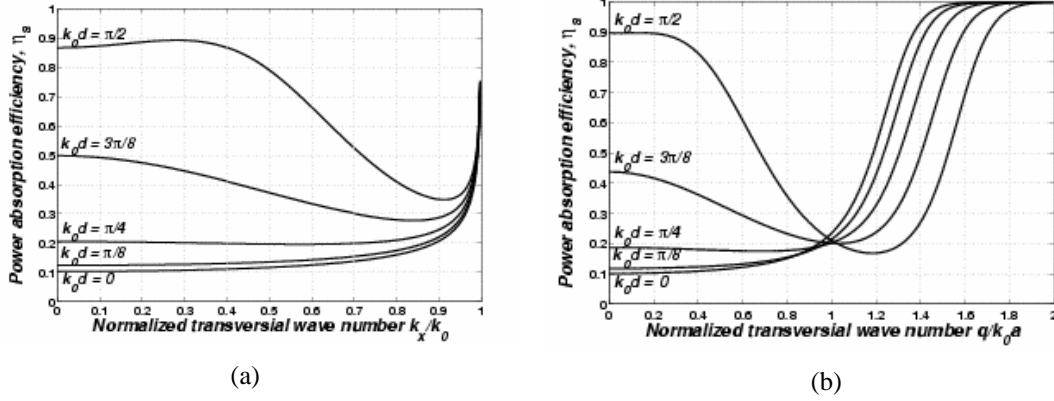

Figure 2: Power absorption efficiency vs. normalized transversal wave number, $Z_1/Z_0 = 0.1140 + j0.0658$: (a) Plane wave model ($k_0 a \rightarrow \infty$) [3], [4], [5], (b) Cylindrical wave model ($k_0 a = 10$).

Noting that Leontovitch and Debye approximations (Table 4) lead to

$$\eta_{a,P}^S \Big|_{\substack{k_x=0 \\ k_0}} = \eta_a^{TEM} \sim \eta_{a,C}^S \Big|_{\substack{q \\ k_0 a} = 0}, \quad (8)$$

where η_a^{TEM} is expressed as [4]

$$\eta_a^{TEM} \sim \frac{2\Re\left\{\frac{Z_1}{Z_0}\right\}\left(1 - \Re\left\{\frac{Z_1}{Z_0}\right\}\right)}{1 - \Re\left\{\frac{Z_1}{Z_0}\right\} - \left(1 - 2\Re\left\{\frac{Z_1}{Z_0}\right\}\right)\cos^2\left(k_0 d + \Im\left\{\frac{Z_1}{Z_0}\right\}\right)}. \quad (9)$$

This results in an asymptotic common lower bound η_a^{TEM} for both models in (7) and renders a tight asymptotic common lower bound for the line-source power absorption efficiencies $\eta_{a,P}^L$ and $\eta_{a,C}^L$ associated with the planar and the cylindrical models, i.e.,

$$\eta_{a,P}^L = \frac{\int_{k_x} \mathcal{P}_a(k_x) \frac{dk_x}{|\beta_0|}}{\int_{k_x} \mathcal{P}_s(k_x) \frac{dk_x}{|\beta_0|}} = \frac{\int_{k_x} \mathcal{P}_s(k_x) \eta_{a,P}^S \frac{dk_x}{|\beta_0|}}{\int_{k_x} \mathcal{P}_s(k_x) \frac{dk_x}{|\beta_0|}} \geq \eta_a^{TEM}, \quad (10)$$

and

$$\eta_{a,C}^L = \frac{\sum_{q=-\infty}^{\infty} \mathcal{P}_{a,q} |H_q^{(2)}(k_0 \rho')|^2}{\sum_{q=-\infty}^{\infty} \mathcal{P}_{s,q} |H_q^{(2)}(k_0 \rho')|^2} = \frac{\sum_{q=-\infty}^{\infty} \mathcal{P}_{s,q} \eta_{a,C}^S |H_q^{(2)}(k_0 \rho')|^2}{\sum_{q=-\infty}^{\infty} \mathcal{P}_{s,q} |H_q^{(2)}(k_0 \rho')|^2} \geq \eta_a^{TEM} \quad (11)$$

respectively.

Finally, in the limit of zero curvature as $k_0 a \rightarrow 0$, the cylindrical model is asymptotically reduced into the planar model, i.e.,

$$\eta_{a,C}^L \sim \eta_{a,P}^L, \quad (12)$$

It is readily noted that while the asymptotic result in (8) is valid if Leontovitch and Debye approximations can be applied, for the validity of (12) requires, in addition, that $a/\rho' \rightarrow 1$ (or equivalently $d/a \rightarrow 0$).

Calculations based on Eq. (5) and Tables 2-3 are now carried out for magnetic line-source excitation (Table 1) utilizing FCC guidelines [14] for evaluation of biological tissues parameters at cellular frequencies (human brain parameters at 900 MHz: $\sigma = 0.7[S/m]$, $\varepsilon_1 = 45\varepsilon_0$). Fig. 3 reveals that the cylindrical model's results correlate well with Eqs. (7)-(12). Furthermore, as expected, the power absorption efficiencies $\eta_{a,C}^L$ for the cylindrical model is tightly bounded from above and below by the power absorption efficiencies associated with the planar model excited by surface and line magnetic currents (Table 1), respectively, for a broad range of $k_0 a$ values, i.e.,

$$\eta_a^{TEM} \leq \eta_{a,C}^L \leq \eta_{a,P}^L, \quad k_0 a > 1. \quad (13)$$

Figure 3: Curvature effect on efficiencies and bounds: FCC parameters at 900MHz [14], $\sigma = 0.7[S/m]$, $\varepsilon_1 = 45\varepsilon_0$.

In conclusion, the power absorption efficiency for the cylindrical model is universally bounded by the planar model efficiencies for both excitations (Table 1), namely, the planar and the line magnetic current sources. Furthermore, as the curvature of the absorbing medium approaches zero, the power relations for the cylindrical model are asymptotically reduced to the results associated with the planar model.

RECOGNITION AND ENGULFMENT OF THE APOTOTIC CELLS: INFLUENCE OF THE EXPOSURE TO MODERATE-INTENSITY STATIC MAGNETIC FIELD

TENUZZO, MAJDI DWIKAT and ALESSANDRA QUARTA**

**DEPARTMENT OF BIOLOGICAL AND ENVIRONMENTAL SCIENCE AND
TECHNOLOGY; UNIVERSITY OF LECCE; LECCE, ITALY**

ABSTRACT

Phagocytosis of the apoptotic cells requires distinguishing features on the surface of dead cells, recognition and tethering molecules, as well as the cytoskeletal and other cellular machinery involved in engulfment.

If the details of the interaction between apoptotic cells and phagocytes are still far to be fully understood, even more obscure are the external factors able to modulate the phagocytosis. We have hypothesized that any factors influencing cell surface molecules expression (phagocyte and /or apoptotic cell) can in turn affect recognition of apoptotic cells. This is indeed the case of static magnetic field of moderate intensity that alters the surface of cells after 24 h of continuous exposure.

Therefore, the recognition of apoptotic lymphocytes by liver sinusoidal cells under exposure to 6 mT static magnetic field to define at which extent static magnetic fields are able to modulate this specific type of phagocytosis was studied.

Carbohydrate expression on lymphocyte surfaces was extensively affected by exposure to static magnetic field irrespective of the cell status, i.e. normal or apoptotic. These modifications are responsible of the altered recognition of apoptotic lymphocytes by the sinusoidal liver cells. In particular, the exposure to static MF has been found to be an extremely critical factor for the recognition of not only apoptotic lymphocytes, but especially for control ones.

INTRODUCTION

The interest in the biological effects of non-ionizing electromagnetic fields (EMFs) on the whole organism, as well as on cellular systems, has considerably increased in recent years in consideration of their increased production (from the generation and transmission of electricity, to domestic appliances and industrial equipment, to telecommunications and broadcasting) and of possible health risk for humans. Findings on the effects of (E)MFs exposure on humans are often contradictory and, therefore, difficult to interpret. No direct evidence of tumorigenicity have ever been demonstrated, however, epidemiological studies have associated (E)MFs exposure with increased incidence of cancer. The multiplicity of experimental conditions (i.e., *in vitro* or *in vivo* models, intensity and type of field, oscillatory or static, time of exposure, metabolic state of the cells, etc) makes contradictory the data on the biological effects of (E)MFs. Many researches have indicated plasma membrane as the primary site of action of (E)MFs (Santoro et al., 1997). Indeed, the effects on plasma membrane have been described at different levels: on the electrochemical balance of the membrane (Panagopoulis et al., 2000), on its surface (Paradisi et al., 1993), on the distribution of membrane proteins (Bersani et al., 1997) and membrane receptors, on the cell-cell and cell-matrix junctions (Somosy, 2000), on lipid peroxidation and generation of reactive oxygen species (ROS) (Ishisaka et al., 2000; Jelenkovic et al., 2006), on DNA damage (Fiorani et al., 1992; Miyakoshi 2005), on the sugar residues on cell membrane (Bordiushkov et al., 2000; Chionna et al. 2003b) and on trans-membrane fluxes of different ions especially calcium (Thompson et al., 2000; Cho et al., 1999 Lyle et al., 1997). As a consequence, cellular processes (physiology and metabolism, i.e. apoptosis, cellular shape, cytoskeleton polymerization) are influenced (Fanelli et al., 1999; Teodori et al., 2002a, b; Chionna et al., 2003a, 2005). In turn, modulation of apoptosis can favor the development of many diseases (Kountouras et al., 2004; Nikitakis et al., 2004).

In particular, apoptosis is an important and widespread process aimed to protect organism by the silent demise of damaged and/or aged cells. Apoptotic cells are usually cleared by phagocytosis *in vivo* with a rapid and efficient process able to remove damaged cells and components by inhibiting inflammation (Savill and Fadok, 2000). The initial event in phagocytosis is the recognition of the target. Successful engulfment requires that apoptotic cells expose at least one “eat-me” signal on their surface (Savill and Fadok, 2000). Apoptosis leads to disruption of the normal phospholipid asymmetry of the plasma membrane, that generates ligands on the cell surface (Williamson and Schleger, 2002), facilitating recognition by specific receptors on the phagocytes. Several *in vitro* study, starting from the pioneering work of Savill et al. (1990), which identified macrophage vitronectin receptor ($\alpha v\beta 3$ integrin) as the first receptor to recognize and engulf apoptotic cells, have characterized several recognition systems, mainly by inhibitory studies of the phagocytic process. Table I summarizes the various “eat-me” signals, so far identified, capping the apoptotic cells, that are recognized simultaneously or alternatively by distinct phagocyte receptor molecules.

Table I: Redundancy in apoptotic cell surface determinants and phagocytes receptors.
Present on

Epitopes and/or receptor	Apoptotic cells surface	Phagocyte surface
phosphatidylserine (PS)	yes	yes
CD31	yes	yes
ATP-binding cassette transporter (ABC1)	yes	yes
phosphatidylserine receptor (PSR)	no	yes
C1q/Mannose Binding Lectin (MBL)	no	yes
calreticulin and CD91	no	yes
CD14	no	yes
$\alpha v\beta 3/\alpha v\beta 5$	no	yes
Scavenger receptors (SRA,CD68,LOX1,CD36)	no	yes
CD11/CD18	no	yes
Lectins	no	yes
Ox-LDL	yes	no
ICAM 3	yes	no
MER	no	yes
$\alpha v\beta 3$ integrin	no	yes
$\beta 2$ -GPI receptors	no	yes

bridging molecules:

Milk Fat Globule Epidermal growth factor 8, (MF-GE8); Growth Arrest Specific gene 6, (Gas6); trombospondin (TSP)

The same “eat-me” ligand can be recognized by different receptors or bridging molecules, so that recognition possibilities are widely amplified. This redundancy aims to assure maximum clearance efficiency and explains the inability of some individual deletions to efficiently impaired apoptotic cell clearance *in vivo*.

In a wide range of phagocytes, both professional and non-professional, carbohydrate changes on the surface of apoptotic cells are important in triggering recognition (Duvall et al., 1985; Dini et al., 1992; Dini, et al.1993). Initially it has been suggested that healthy hepatocytes ingested apoptotic ones via the asialoglycoproteins receptor, that is exclusively present on the parenchymal liver cells (Dini et al., 1992). Galactose and mannose- specific receptors of sinusoidal liver cells have been also found play a role in the recognition and engulfment of apoptotic cells, mostly blood circulating (Dini, et al. 1995; Falasca, et al. 1996; Dini and Carlà, 1998), likely in cooperation with other hepatic carbohydrate-specific receptors. Indeed, the mannose receptor of macrophages and liver endothelial cells is the best characterized member of a family of surface lectin receptors that mediates binding and internalization of mannose and fucose (Duvall et al., 1985; Dini et al., 1992; Dini, et al.1993; Dini et al., 1995). CD14, a multifunctional receptor known originally for its role as the lipopolysaccharide (LPS) receptors (Gregory, 2000), could bind the carbohydrate groups that are exposed during the apoptosis.

The overall environmental generation of (E)MFs is due to both natural and artificial sources. Thus, many cell functions can be influenced by the accidental or intentional exposure to (E)MFs. It is likely

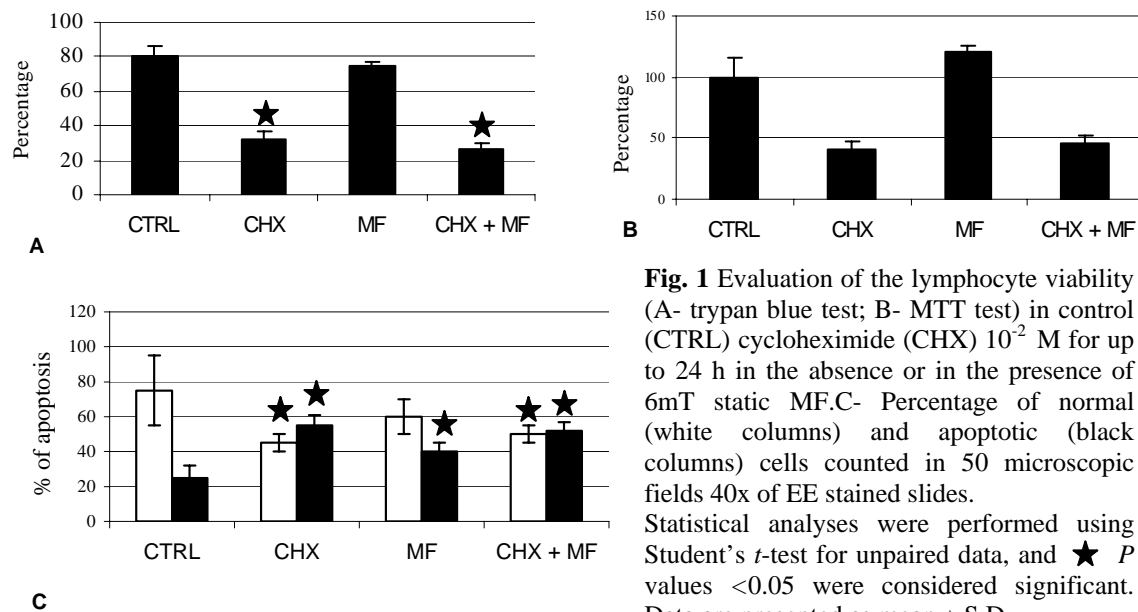

that recognition of apoptotic cells could be affected by any environmental factors able to modulate cell surface molecules expression, irrespectively on phagocyte and /or apoptotic cells. Among all the possible factors present in the environment static magnetic field of moderate intensity (static MF 6 mT of intensity) are also included. While it has been reported that static MF can alter surface of cells after 24 h of continuous exposure (Chionna et al. 2003b; 2005), scarce and very contradictory are the data of literature regarding the effects of (E)MFs on phagocytosis (Flipo et al. 1998; Simko et al. 2001).

Aim of the present work has been the study of the *in situ* liver recognition of normal or apoptotic lymphocytes that have been exposed for up to 24 h to 6 mT static MF, to define at which extent static MF are able to modulate this specific type of phagocytosis. In particular, liver is the main site for apoptosis of blood cells, is for lymphocytes either a battlefield or a graveyard (Sun and Shi, 2001; Crispe et al., 2000).

Characterization of cell surface of isolated human lymphocytes: apoptotic versus static MF exposed

Human lymphocytes cells were obtained after Ficoll gradient separation of buffy coats from blood donations of non-smoker healthy males, aged 25–45. They were separated from monocytes by double adherence to plastic. During and after the treatments, they were maintained at a cell density of 1×10^6 cells/ml in complete culture medium at 37 °C supplemented with 10% inactivated fetal calf serum (FCS), 2 mM l-glutamine, 100 IU/ml penicillin and streptomycin in a humidified atmosphere of 5% CO₂; cells were used on the first day of explant. Cell viability was more than 95% at the end of the isolation procedure and it was reduced of about 55 and 70% when cells were induced to apoptosis by using heat shock at 43 °C for 1 h followed by 4 h recovery in fresh medium or cycloheximide (CHX) 10^{-2} M for up to 24 h. The exposure to static MF of 6 mT of intensity, up to 24 h, did not induce any reduction of the cell viability nor modification of cell growth (Fig. 1). Static MF was produced by Neodymium magnetic disks (10 mm in diameter and 5mm in height) of known intensity supplied by Calamit L.td (Milano, Italy) placed under the culture Petri dishes. The intensity of the field generated by the magnet was checked by means of a gaussmeter with a range of operating temperature of 0°C to 50°C and an accuracy (at 20°C) of $\pm 1\%$ (Hall-effect gaussmeter, GM04 Hirst Magnetic Instruments Ltd, UK). The laboratory areas between incubators, worktops and tissue culture hood measured 0.08 μ T to 0.14 μ T (50 Hz) magnetic fields. In the room the background flux density was 10 μ T (static) and the local geomagnetic field was approximately 43 μ T.

However, when apoptosis was induced under exposure to static MF, the percentage of dead cell was reduced of about 15-20% (Fig. 1). Morphological observation confirmed these results. Indeed, exposure to static MF affected cell shape and surface. Microvilli of control cells became lamellar and cells was more elongated. The surface of lymphocytes induced to apoptosis under exposure was less smooth than not exposed ones (Chionna et al. 2003a).

The liver phagocytosis of apoptotic lymphocytes is mediated by carbohydrate-specific receptors (Dini 2005). In fact, the cell surface of apoptotic lymphocytes express normally hidden sugar moieties like

D-galactose, Mannose, N-acetyl-Dgalactosamine, N-acetyl-Dglucosamine, Fucose. Cells, fixed with 4% formalin in phosphate buffer pH 7.4, 5 min, were labelled with lectin-FITC conjugates, i.e. Concanavalin-A (Con-A) (D-mannose) (40 µg/ml) and Ricinus communis (D-galactose) (2 µg/ml), 30 min in the dark.

Both the apoptotic treatment and the exposure to 6 mT static MF influenced the sugar expression; in addition exposure to static MF modified fluorescence pattern and intensity with respect to the corresponding non exposed cells. In table II are summarized the semiquantitative evaluation of different carbohydrate exposure on cell surfaces of normal, apoptotic and static MF exposed lymphocytes, analyzed with fluorescence microscopy. The carbohydrates whose expression is enhanced after exposure are mannose/D-glucosamine and galactose/D-galactosamine, while the fluorescence pattern resulted modified for all lectins.

Liver recognition and internalization of lymphocytes

The quantification of adhesion and internalization of the *in situ* injection of normal, apoptotic and static MF exposed lymphocytes to mouse liver sinusoidal walls is reported in fig. 2. Male Swiss mice, weighting 15-20 g were maintained on a standard laboratory diet and free water access. Before surgery, animals were anaesthetized by an i.p. injection with Farmotal (barbiturate anaesthetic) (Farmitalia, Italy), 10 mg/100g body weight. All animals received humane care according to the criteria outlined by the national law. For each set of experiments at least three animals were used. Livers were perfused in a non-recirculating system at a flow rate of 1ml/min. 1×10^6 lymphocytes labelled with Hoechst 33342 were injected into the liver circulation (total volume 10 ml). Lymphocytes used in the different experiments were control, apoptotic, control static MF exposed and induced to apoptosis under static MF. The livers were then extensively washed with culture medium to remove unbound cells. Livers, fixed in 4% paraformaldehyde in phosphate buffer, were processed for routine light microscopy or for cryosectioning. The adhesion of lymphocytes to the sinusoidal wall was evaluated by light and fluorescent microscopy of liver sections. The adhesion specificity was tested in parallel inhibition experiments by adding 80 mM (final concentration) of a sugar cocktail (N-acetyl-D-galactosamine, Mannose, fucose, N-acetylglucosamine) into the perfusion tube before adding apoptotic lymphocytes. To allow internalization warmed solution (37°C) were used. The concentration of lymphocytes used for all experiments was at saturation point, as evaluated by the presence of apoptotic lymphocytes in the medium collected from the liver.

Liver cells were very active in blocking apoptotic lymphocytes, leaving away normal one (less than 6 % of injected cells were bound to sinusoids). Apoptosis was estimated by morphological analysis at the optical level. Light microscopic analysis of apoptosis was done on haematoxylin/eosin stained cells on slides. Haematoxylin-eosin slides were examined for the scoring of cells undergoing apoptosis, by counting in 50 to 100 high-power microscopic fields (x40). Approximately 300 nuclei per slides were counted. The number of apoptotic cells was expressed as number per microscopic field 40x. Slides were also observed for the presence anomalies in the morphologies (normal or altered shape).

Apoptotic lymphocytes were retained by sinusoidal liver cells at high degree, and when internalization was allowed (i.e. perfusion at 37°C), they were found inside the cells. Worth noting, control non exposed lymphocytes were never phagocyted. Surprisingly, when normal lymphocytes were exposed for 24 hr to static MF, they were retained by sinusoidal walls (three times with respect to control) (fig.2) and internalized when allowed.

The percentage of lymphocytes induced to apoptosis under exposure to static MF bound to sinusoidal liver cells was higher than the apoptotic ones. Correspondingly the number of internalized apoptotic lymphocytes was increased. The induction of apoptosis and static MF exposure had a synergic effect. The recognition of apoptotic lymphocytes was, in all cases, specific as indicated by the inhibition experiments. In fact the clearance of apoptotic lymphocytes was mediated by specific receptors, most likely mannose and galactose, able to recognize the surface modifications. Indeed, liver periportal

sinusoidal tracts express higher amount of mannose and galactose-specific receptors than perivenous sinusoidal tracts, thus leading the periportal liver sinusoids to recognize and internalize more apoptotic lymphocytes than the corresponding perivenous cells (Fig.2). Worth noting, the control static MF -exposed cells were recognized at the same extent in the perivenous and periportal tract of the liver sinusoids. The sugar inhibition experiments indicated a synergic recognition between lectin like receptor and not yet known receptor, since the reduction of binding was only partial prevented (Fig. 2).

Fig. 2 Number of control or CHX 10^{-2} M for up to 24 h treated lymphocytes in the absence or in the presence of 6 mT static MF for 24 h, adhering (white columns) or internalized (black columns) by liver sinusoidal cells. Statistical analyses were performed using Student's *t*-test for unpaired data, and ★ *P* values <0.05 versus CTRL were considered significant. Data are presented as mean \pm S.D.

Analysis of membrane proteins of static MF exposed lymphocytes

The protein pattern of membrane of normal, apoptotic and static MF exposed lymphocytes is reported in fig. 3. Western blot analysis were performed according to Towbin et al. (1979) (Fig.). Specific lectins conjugated to biotin were used: lectin from Concanavalin A specific for α -Mannose and α -glucose residues (at a concentration of 50 μ g/ml), lectin from *Helix pomatia* specific for N-acetyl- α -D-galactosaminyl residues (at a concentration of 50 μ g/ml), lectin from *Triticum vulgaris* specific for N-acetyl- β -D-glucosaminyl residues and N-acetyl- β -D-glucosamine oligomere, (at a concentration 50 μ g/ml), and lectin from *Ulex Europaeus* specific for L-Fucose residues (at a concentration 30 μ g/ml) (Sigma-Aldrich, Saint Louis, MO, USA). Specific binding of the lectins was detected using streptavidin conjugated to peroxidase (1:1,500 dilution) and visualized using 3-3' diaminobenzidine (DAB) as a substrate in the presence of H_2O_2 . Quantification of the glycoprotein bands was performed by using a Biorad Model GS 700 Imaging densitometer.

Differences between exposed and non exposed cells and between control and apoptotic ones have been detected. Apoptosis as well as exposure to static MF induced modifications in the protein profile of cells. In particular, from gel electrophoresis three bands underwent major modifications: 130, 95 and 45-43 kDa, while a fourth band was only found in control exposed cells, 60 kDa. The control exposed and the apoptotic non exposed lymphocytes showed an increment of the band of 43KDa. Conversely, the bands of 95 and 130 KDa increased in the presence of static MF while decreased with the CHX treatment. The intensity of the 45KDa band decreased with the treatments respectively with the incubation of CHX, exposure to static MF and CHX incubation in presence of static MF (Fig. 3).

By using different lectins (Concanavalin-A, *Ulex europaeus* and *Triticum vulgaris*) the expression of glycidic residues of the proteins was evaluated. The western blots for α -Mannose and α -glucose (Con A) has shown 6 different bands (Fig.5). The 100 KDa α band was modified (+8% versus control) only in the samples incubated with CHX under static MF. The 100 KDa β band was modified at the same extent (- 15%) in both samples exposed to static MF or CHX treated. CHX incubation reduced of about 10% the intensity of the 70 KDa γ band with respect to control. Similar pattern (-8%) was found for 65 KDa δ band, while only the samples exposed to static MF showed a decrement (-9%) of 55KDa ϵ band. The 30 KDa ζ band was unchanged. The western blots for α -L-Fucose (*Ulex europaeus*) has shown that the majority of proteins belong to the low molecular weight. Modifications of optical densitometry

with the relative increment or decrement given in percentage with respect to control are reported in fig. 4. The western blots for N-acetyl-D-glucosamine and N-acetyl-neuroaminic (*Triticum vulgaris*) has shown that the majority of proteins belong to the high molecular weight. Optical densitometry with the relative percentage increments with respect to control are reported in fig.4.

In the present work data have been shown on the strong and reproducible effects that the exposure to static MF exerts on the process of liver phagocytosis of apoptotic lymphocytes.

Liver clearance of apoptotic lymphocytes is a complex mechanism that can be influenced at least at three different levels: phagocyte receptors, apoptotic cell quality and static MF exposure. On the side of the phagocyte receptors, in general, the efficiency of phagocytosis is proportional to the number of expressed receptors. In the liver this aspect is particular evident, since the receptors involved in the recognition of apoptotic cells are modulated in relation to the type of the cells (i.e. Kupffer, endothelial cell, hepatocytes) (Dini and Kolb-Bachofen, 1989), to the physiological or pathological status of the organ and to the cell localization inside the lobule (Dini et al., 2002; Dini, 2000; Dini and Carlà, 1998). With respect to this latter aspect, the efficiency of recognition and internalization is higher in the periportal tracts of the liver lobule, than in the perivenous ones, according to the number of carbohydrate specific receptors.

On the side of the edible cells, the quality of apoptotic cells can determine the efficiency of clearance by the liver (Chionna et al., 2003a). It is known that the step in the process of apoptosis (i.e. early, mature or late apoptosis) has influence on the efficiency of removal since the modification of the cell surface changes accordingly with the progression through the apoptotic program (Chionna et al., 2003a). A hierarchy of the expression of specific epitopes on the cell surface of apoptotic lymphocytes has been reported (Chionna et al., 2003a). Therefore, the cell surface of dying cells is progressively changing leading to widely amplified possibilities of a safe recognition and to modulation in the rate of recognition and engulfment. The third level is given by the perturbation exerted by exposure to static MF of moderate intensity. In previous works (Chionna et al., 2003b, 2005; Dini and Abbro 2005; Tenuzzo et al. 2006) we have described the interference of static MF with the process of apoptosis, with cell shape and surfaces, with Calcium ions concentrations, cytoskeleton, differentiation and in the present work, on the liver clearance of normal and apoptotic lymphocytes. Our data confirm those in the literature indicating that cell membranes are the preferential site for the action of the (E)MF (Panagopoulos et al., 2000; Paradisi et al., 1993; Bersani et al., 1997; Somosy, 2000).

By using two different experimental approaches, lectin cytochemistry and western blotting of glycoproteins, the modifications of the sugars moieties and/or the glycoproteins of membranes were shown. Apparent discrepancies between lectin cytochemistry and western blots analysis can be due to the labeling of glycolipids of the plasma membranes with cytochemistry methods.

The identification of the (glyco)proteins whose amount has been modified by the exposure to static MF is currently under investigation. Many of the possible candidate belongs to the transduction pathways and to the adhesion molecules: they are, therefore, molecules that can be involved in the process of

recognition, cell-cell adhesion and the intracellular pathways; processes that are all important for the recognition and engulfment. Indeed, it is not possible to define if the modifications in the cell proteins are due to conformational changes, to transductional or transcriptional modifications or to a synergic effects of all these factors.

To date, the very few data that have been published on the effects of static MF on gene expression are confusing and, none of them is referring to genes regulating the apoptotic program. Indeed, some studies obtained by using electromagnetic fields at diverse intensities, i.e. ELF and EMF, reported effects on gene expression, particularly at the transcriptional level, after exposure to ELF and EMF of human HL60 (Goodman et al., 1992). Several specific transcripts, i.e. actin, tubulin, H2B histone, c-myc, increased their expression by two to three fold after 20 min of exposure (De Mattei et al., 2005). Conversely, in other reports (Hirose et al., 2003) the exposure to homogeneous static MF at 10 T was unable to affect the expression of c-Jun, c-Fos and c-Myc, while the inhomogeneous static MF at 6T significantly increased c-Jun expression but only at the long-time exposure.

The most intriguing data that has been here shown is the ability of sinusoidal liver cells to retain and to internalize normal exposed lymphocytes. One possible reason of this recognition can be the modifications exerted by static MF on the surface of lymphocytes that share changes with apoptotic cells, thus leading to the removal of control exposed cells via receptors used for the clearance of apoptotic lymphocytes.

It is worth noting to mention that the process of recognition and engulfment of the apoptotic cells has same peculiarity that makes the process of phagocytosis of apoptotic cells different from the phagocytosis of microorganisms or debris (Krysko et al., 2003). In fact, in non-pathological conditions, an efficient clearance is assured by the redundant interaction between apoptotic cell ligands and multiple molecules present on the engulfing cell surface. The apoptotic cell engulfment appears to activate signals able to suppress release of pro-inflammatory cytokines, thus pro-inflammatory responses are not elicited. The phagocytosis of apoptotic cells prevents inflammation (Maderna and Godson, 2003). Therefore, it should be further investigated if the removal of static MF exposed lymphocytes share the characteristic of the phagocytosis of apoptotic cells.

SUMMARY

In summary, evidences of the perturbation exerted by the exposure to 6 mT static MF of human isolated lymphocytes have been reported. In particular, the static MF exposure impaired the apoptotic rate and gave rise to modifications of the cell surface in normal exposed cells similar to the cell surface modifications achieved during the apoptotic program. The cell surface modifications of apoptotic cells are important for their fast and silent removal by professional and amateur phagocytes. Interestingly, the same liver receptorial systems are also used for the recognition of control exposed lymphocytes. The pathological and/or physiological implications are not yet understood and need to be further investigated.

Data showed that the recognition of apoptotic lymphocytes by the sinusoidal liver cells is affected by the exposure to static MFs. Interestingly, exposure to static MFs has been found to be an extreme critical factor not only for the recognition of apoptotic lymphocytes but also for control ones. The implication for human health needs to be deeply investigated.

EFFECTS OF HYDROGEN PEROXIDE AND ADP-RIBOSE ON THE ACTIVATION OF TRPM2 CATION CHANNELS

MUSTAFA NAZIROĞLU

Department of Biophysics,, Faculty of Medicine, Suleyman Demirel University, Isparta, Turkey (mnaziroglu@med.sdu.edu.tr)

Abstract:

It is well known that microwaves from cellular phones or other sources may affect biological systems by increasing free radicals, which may enhance lipid peroxidation levels of the cells, thus leading to oxidative damage. Hydrogen peroxide (H_2O_2) produces during oxidative stress. The Na^+ - and Ca^{2+} -permeable melastatin related transient receptor potential channel TRPM2 cation channels can be gated either by adenosine diphosphoribose (ADP-ribose) in concert with Ca^{2+} or by H_2O_2 , an experimental model for oxidative stress, binding to the channel's enzymatic Nudix domain. Since the mechanisms that lead to TRPM2 gating in response to ADP- ribose and H_2O_2 are not understood, we tested the effects of various antioxidants on ADP-ribose, NAD^+ and H_2O_2 -induced TRPM2 currents.

Chinese hamster ovary (CHO) cells were transfected with cDNA coding for TRPM2. Cells were studied with the conventional whole-cell patch clamp technique. The intracellular solution used EDTA (10 mM) as chelator for Ca^{2+} and heavy metal ions. H_2O_2 (10 mM) was added extracellularly although the ADP- ribose (0.3 mM) and NAD^+ (1 mM) were applied intracellularly (i.e. through the pipette).

Non-selective cation currents in whole cell experiments were consistently induced by ADP- ribose, NAD^+ and H_2O_2 . The time course of ADP- ribose and NAD^+ was characterized by a delay of 0.6-3.0 min and a slow current induction to a plateau although the time course of H_2O_2 was characterized by a delay of 2-5 min and it didn't reach a slow current induction to a plateau

These results demonstrated that all three agonists, H_2O_2 , ADP- ribose and NAD^+ , are capable of activating TRPM2. The three agonists are likely to interact directly with TRPM2 channels, consistent with the idea that they bind to the nudix domain.

Introduction

Daily exposures to various types of magnetic fields are increasing in human environment. Extremely low frequency microwaves (MW) from power lines and public transportation systems, high- frequency MW from mobile phones and computers, and strong MW from magnetic resonance imaging in medical diagnosis are the most familiar sources of exposure. Possible biological effects due to exposure various types of MW have become of considerable public interest and concern (McCann et al., 1993; Murphy, 1993).

Reactive oxygen substances (ROS) and lipid peroxides are produced by a free radical chain reaction, which can also be initiated by ROS. The ROS, i.e. singlet oxygen, superoxide anion radical, perhydroxyl radical and hydroxyl radical, contribute to tissue damage (Halliwell and Gutteridge, 1999). ROS also cause injury by reacting with biomolecules such as lipids, proteins and nucleic acids as well as by depleting enzymatic and/or nonenzymatic antioxidants in the brain (Baydaş et al., 2003; Koylu et al., 2006). ROS and/or free radicals may be involved in the action of MW on biological system (Irmak et al., 2002; İlhan et al., 2004; Koyu et al., 2005; Koylu et al., 2006). Antioxidant treatments in animals and humans could be beneficial in preventing or reducing some complications of low frequency MW (İlhan et al., 2004; Koyu et al., 2005; Koylu et al., 2006).

Transient receptor potential (TRP) channels were first described in *Drosophila*, where photoreceptor carrying *trp* gene mutations exhibit a transient voltage response to continuous light (Clapham, 2003). These are subdivided into three major subgroups, namely, the vanilloid receptor family, the short TRP channels and melastatin (or long) TRP channels (Kolisek et al., 2005). We have become particularly interested in one member of latter family, known as TRPM2, for a number of reasons a potential role in cell death resulting from oxidative stress (Wehage et al., 2002).

Although TRPM2 is dominantly expressed in brain, it is also detected many other tissues, including bone marrow, spleen, heart, leukocytes, liver, and lung. Native TRPM2 currents have been recorded from U937 monocyte cell line (Perraud et al., 2001), neutrophils (Heiner et al., 2003), and CRI-G1 insulinoma cells (Togashi et al., 2006) where ADP- ribose induces large cation currents that closely match those mediated by

heterologously expressed TRPM2. The Intracellular Ca^{2+} appears to be an important modulator and cofactor of TRPM2, as elevated intracellular Ca^{2+} can significantly increase the sensitivity of TRPM2 toward ADP-ribose (Wehaga et al., 2002; Hara et al., 2002; Kolisek et al., 2005). The channel in human embryonic kidney (HEK)-293 cells can also be gated by H_2O_2 , a model substance used as paradigm for oxidative stress (Wehaga et al., 2002; Fonfria et al., 2004; Kolisek et al., 2005). There are conflict reports on the mechanism of H_2O_2 -mediated gating of TRPM2. The mechanism has been proposed to be direct or independent ADP-ribose (Wehaga et al., 2002; Hara et al., 2002; Heiner et al., 2003; Kolisek et al., 2005). More recent evidences suggest an indirect mechanism, because H_2O_2 releases ADP-ribose from mitochondria (Fonfria et al., 2004; Kolisek et al., 2005). However, molecular mechanisms of H_2O_2 gates the TRPM2 channels cells are unclear and warrant further studies.

The molecular mechanism by oxidative stress leads to opening of TRPM2 channels need to be elucidated in detail. To study the role of TRPM2 in oxidative stress we used an experimental model, H_2O_2 , was applied to TRPM2-transfected cells. Furthermore, the present study was aimed at elucidating the role of the ADP-ribose and NAD^+ for gating TRPM2 channels in the chinese hamster ovary (CHO) transfected cells.

Material and methods

Cell culture and transfection

CHO cells were obtained from A.T.C.C. (Rockville, MD, U.S.A.). The cells were cultured in Ham's medium (1 x) (Biochrom, Berlin, Germany), supplemented with 10% (v/v) fetal calf serum (Biochrom), 1 mM sodium-pyruvate (Sigma) and 4 mM L-glutamine (Biochrom, Berlin, Germany). Penicillin (50 U/ml)-streptomycin (50 mg/ml) combination in single-cell experiments was added to the medium. Cells were plated onto Poly-Lysin (0.1 $\mu\text{g}/\mu\text{l}$, Sigma) coated glass coverslips for 24 h and then transiently transfected with one of the described pcDNA3-EGFP-channel-vector constructs (5 μg) and TransFast Transfection Reagent (7.5 μl ; Promega, Mannheim, Germany). As controls, cells were transfected with 2.5 μg „empty“ vector-construct and 3.75 μl TransFast Transfection Reagent. Electrophysiological studies were carried out 24-48 h after transfection in cells visibly positive for EGFP.

Electrophysiology

Patch clamp techniques have been described in detail elsewhere (Wehaga et al., 2002; Naziroğlu et al., 2006). Transfected cells were studied with the patch-clamp technique in the whole-cell mode, using a EPC 9 equipped with a personal computer with Pulse and X chart software (HEKA, Lamprecht, Germany). The standard extracellular bath solution contained (in mM) 140 NaCl, 1.2 MgCl_2 , 1.2 CaCl_2 , 5 KCl, 10 HEPES, pH adjusted with KOH to 7.4. For Na^+ free solutions, Na^+ was replaced by NMDG (150 mM) and the titration was performed with HCl. For the NMDG solutions with Ca^{2+} , NMDG was partly replaced with CaCl_2 (11.2 mM), preserving an osmolarity of about 300 mosmol/l. The noise level in all experiments was minimised by coating the patch electrode tip with agarose (GibcoBRL, Paisley, Scotland). The pipettes for whole cell recordings were filled with a solution composed of (in mM) 145 Cs-glutamate, 8 NaCl, 2 MgCl_2 , 10 EGTA, 10 HEPES, pH 7.2 (adjusted with CsOH). In some experiments, the pipette solution additionally contained ADP-ribose (0.3 mM) or NAD^+ (final concentration 1 mM, added to the pipette solution from a stock of 70 mM in ethanol). Heavy metal concentration of internal buffer affected activation of the channels by H_2O_2 . In whole cell experiments, the pipette solution added 10 mM EDTA for EGTA. Cells were held at a potential of -60 mV, and current-voltage (I-V) relations were obtained from voltage ramps from -90 to $+60$ mV applied over 400 ms. ADP-ribose, NAD^+ and H_2O_2 and all other chemicals were obtained from Sigma.

Data are expressed as mean \pm SD. Statistical significance between groups were assessed with Student's t-test. A $p < 0.05$ value was considered significant.

Results

In a previous study (Wehaga et al., 2002), authors have characterized TRPM2 currents in TRPM2-transfected HEK-293 cells. The currents were consistently activated by intracellular ADP-Ribose and also by extracellular H_2O_2 , but the latter stimulus was effective in only about 25 % of the experiments. A further stimulus of TRPM2 channels, intracellular NAD^+ failed in HEK-293 cells. In a further study, we have transfected TRPM2 channels into CHO cells and could stimulate them also with NAD^+ ; however, no stimulation with H_2O_2 was possible. In the present experiments, we again chose CHO cells but changed the intracellular buffer that used now EDTA rather than EGTA as chelator for Ca^{2+} and probably contaminating

heavy metal ions. Moreover, we chose an intracellular Ca^{2+} concentration calculated to be in the range of 1 μM . Using these conditions, we were able to evoke TRPM2 currents consistently with either of the three stimuli, intracellular ADPR (0.3 mM), intracellular NAD (1 mM), and extracellular H_2O_2 (10 mM) (Figures. 1A and B, 2A and 2B). The currents were non-selective cation currents with a reversal potential close to 0 mV, as previously found to be typical of TRPM2 currents, and were readily blocked in the inside direction when the Na^+ in the bath was replaced by the large impermeant cation NMDG⁺. No such currents were ever observed when cells were studied that were transfected with a vector only but not with TRPM2; such negative control data were obtained on every experimental day studying TRPM2.

The values for the current densities were $1.87 \pm 0.98 \text{ pF}^{-1}$ (n=4) and (- 60 mV holding potential) in the absence of NAD⁺ and ADP- ribose, $29.16 \pm 10.57 \text{ pF}^{-1}$ (n=5) and $31.45 \pm 23.16 \text{ pF}^{-1}$ (n=5) in the presence of NAD⁺ and ADP-ribose in the patch- pipette, respectively (Figure 3). The times elapsed before the full response to ADP- ribose and NAD⁺ occurred varied between 0.6 -3.0 min. This variability is probably caused by variable diffusion times of ADP- ribose and NAD⁺ from pipette bath into cytosol and by metabolism of ADP- ribose and NAD⁺ to products that do not activate TRPM2 (Perraud et al., 2001; Wehega et al., 2002); metabolism is expected to delay activation of TRPM2 particularly when diffusion is already slow.

The ADP- ribose- and NAD⁺ induced inward currents was abolished when extracellular Na^+ was substituted with the large impermeable cation NMDG ((Figures. 1A and B, 2A and 2B). When Ca^{2+} (10 mM) was added to NMDG, a small inward current was restituted (Figures 1B, C and 2B, C). These data indicate that TRPM2 enables non- selective cation currents carried mainly Na^+ , but to a small part also by Ca^{2+} , in inward direction and carried by Cs^+ in the outward direction under our experimental conditions. Our results with TRPM2 are essentially identical reports (reviewed in Kuhn et al., 2005).

Figure 1. Stimulator role of intracellular ADP-ribose on the currents of TRPM2 channel. The time where the whole cell period where the normal bath solution (140 mM Na^+) was exchanged to a solution with NMDG as main cation (150 mM, no Ca^{2+} present). The holding potential was -60 mV. **A.** Original recordings from control cell. **B.** Ca^{2+} selectively of TRPM2. A cell expressing TRPM2 currents stimulated with ADP-ribose (0.3 mM) in the pipette. **C.** Current voltage relationships of ADP- ribose currents through TRPM2 in presence of various extracellular cation (same experiments as in panels B).

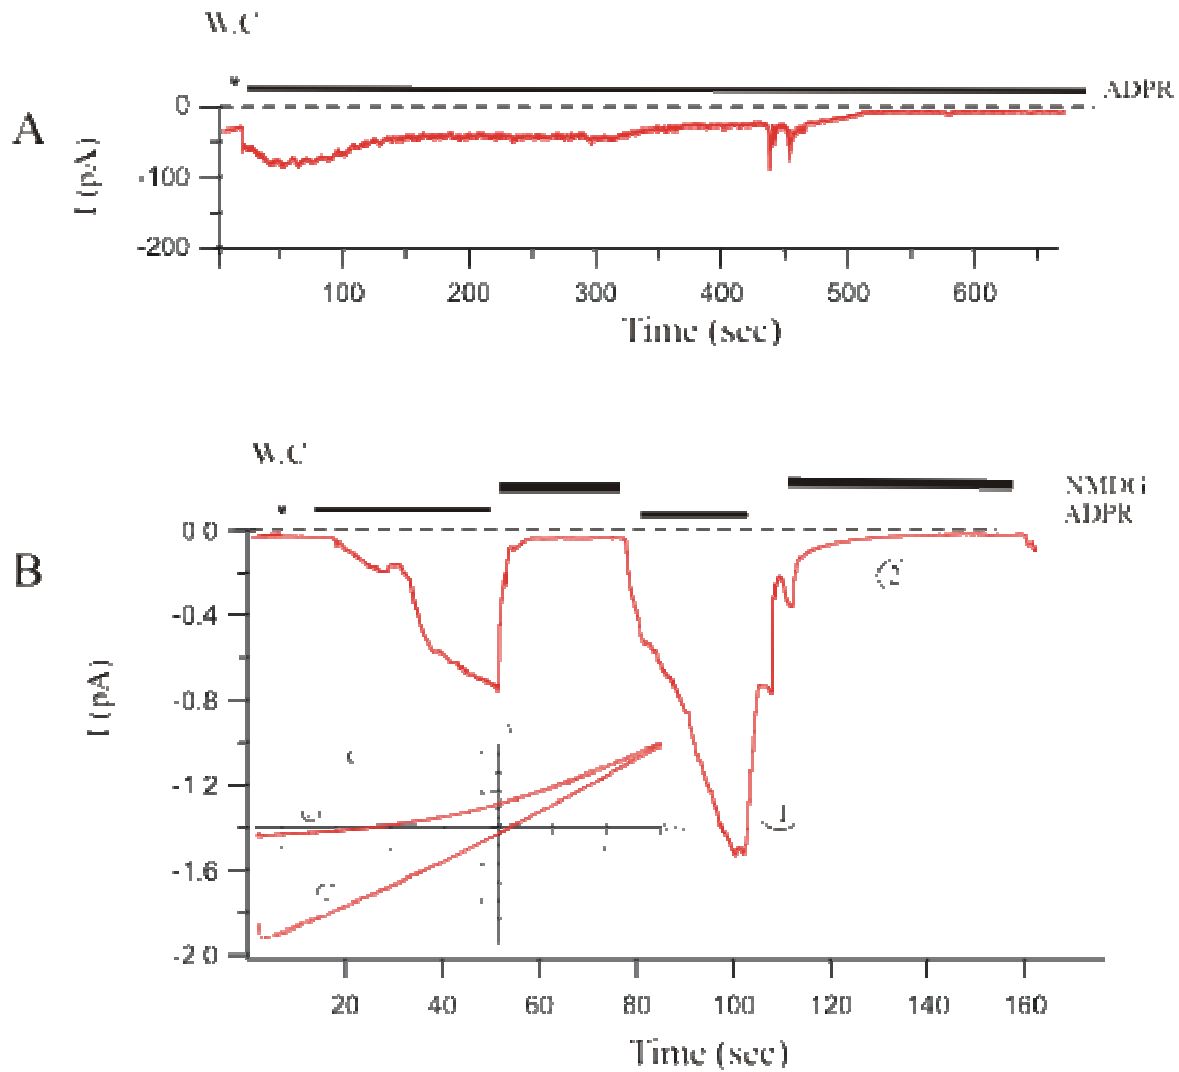

Figure 2. Stimulator role of intracellular $\beta\text{-NAD}^+$ on the currents of TRPM2 channel. The time where the whole cell period where the normal bath solution (140 nM Na^+) was exchanged to a solution with NMDG as main cation (150 mM, no Ca^{2+} present). The holding potential was -60 mV. **A.** Original recordings from control cell. **B.** Ca^{2+} selectivity of TRPM2. A cell expressing TRPM2 currents stimulated with $\beta\text{-NAD}^+$ (1 mM) in the pipette. **C.** Current voltage relationships of $\beta\text{-NAD}^+$ currents through TRPM2 in presence of various extracellular cation (same experiments as in panels B).

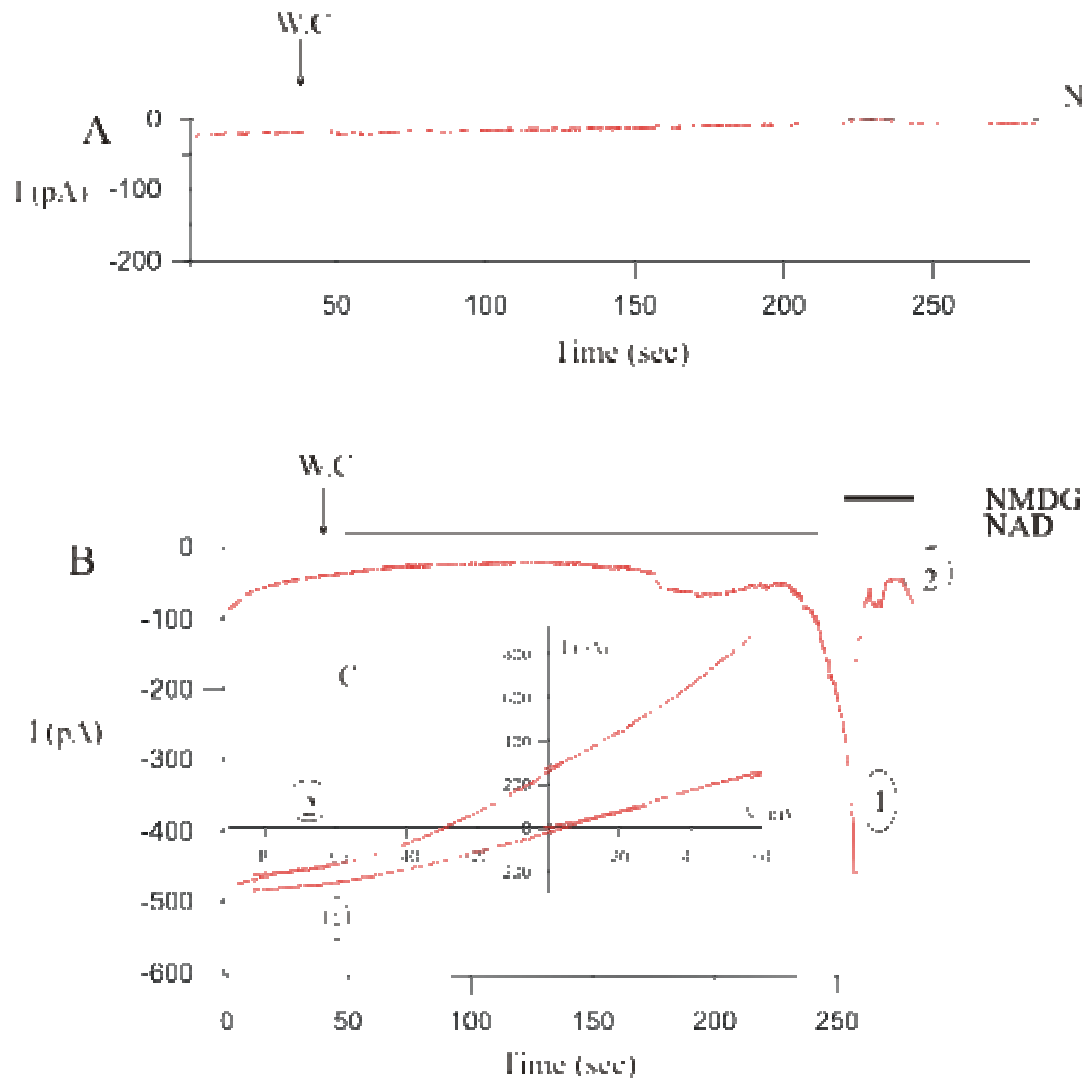

Figure 3. Stimulation of TRPM2 with intracellular β -NAD⁺ (1 mM) and ADP-Ribose (0.3 mM). For each of the two applicants studied and for pcdfgp (control- transfected cells), the initial current density (current amplitude at -60 mV, divided by the cell capacitance, a measure of cell size as well as maximal current density after dialysis with β -NAD⁺ and ADP-Ribose was allowed. The numbers of parentheses indicate the number of cells studied; significant stimulation of currents is indicated with *asterisk*. (mean \pm SD).

Activation of TRPM2 currents by H_2O_2

It has been well established that mitochondria produce most of the endogenous ROS, including H_2O_2 , through oxidative stress. It is therefore rational to propose that the exogenously or endogenously produced ROS via oxidative stress could impair TRPM2 channel function. As a model of oxidative stress, we tested the effects of extracellular H_2O_2 on the TRPM2 channels. H_2O_2 was added to the bath to a final concentration of 10 mM. After a delay of 2-5 min, an inward current developed gradually that was blocked by NMDG and was partly carried by Ca^{2+} . After wash-out of H_2O_2 , the current initially increased further but then declined almost to the baseline levels although a small NMDG-sensitive current was still present (data were not shown). Re-addition of H_2O_2 led to a second current rise. When the cells were exposed to H_2O_2 over more extended times than in Figure 3, the inward currents did not reach a plateau after even 15 min (data were not shown). These data suggest a participation of ROS in the TRPM channel regulation by oxidative stress.

Stimulation currents with H_2O_2 after a characteristic delay was consistently observed more than 16 cells expressing TRPM2. The mean increase in current density was -3.8- to -13.2 (Figures 4). The time elapsed before the full response to H_2O_2 occurred varied between 2-5 min.

Figure 4. Stimulation of TRPM2 with extracellular H_2O_2 (10 mM). For each of the two applicants studied and for pcdgfp (control- transfected cells), the initial current density (current amplitude at -60 mV, divided by the cell capacitance, a measure of cell size as well as maximal current density after dialysis with H_2O_2 was allowed. The numbers of parentheses indicate the number of cells studied; significant stimulation of currents is indicated with *asterisk*. (mean \pm SD).

Discussion

The present study was examined effects of H_2O_2 , ADP- ribose and NAD^+ on activation of TRPM2 channel. The present study found that the non- selective cation channel currents induced by H_2O_2 , ADP- ribose and NAD^+ .

NAD^+ has been reported to stimulate TRPM2 (Sano et al., 2001; Hara et al., 2002). We saw the activation of TRPM2 by NAD^+ , which support the idea that this substance activates TRPM2 directly. TRPM2 contains as a characteristics structural feature a Nudix domain in its C- terminal cytosolic tail (Perraud et al., 2001). A nudix domain is a consensus region that has been known for a class of pyrophosphatases that degrade nucleoside diphosphates (Heiner et al., 2003). Indeed, the nudix domain of TRPM2 cleaves ADP- ribose, a breakdown product of NAD^+ and cyclic ADP- ribose, representing an intracellular second messenger stimulating calcium release mediated by ryanodine receptors. While ADP- ribose is hydrolyzed by TRPM2, it is also activates TRPM2 and induces TRPM2 currents during infusion of ADP- ribose by the patch pipette (Harteneck, 2005). NAD^+ has been reported that to stimulate TRPM2 (Hara et al., 2002).

Activation of TRPM2 by H_2O_2 has been reported from two approaches. One group suggested to gate the channel independently of ADP- ribose (Fonfria et al., 2004; Perraud et al., 2005) and the activation of TRPM2 by H_2O_2 is probably linked to the activity of the poly(ADP- ribose) polymerase (PARP-1), an enzyme transferring multiple ADP- ribose groups to proteins. Evidence for this intracellular pathway resulting in TRPM2 activation has been confirmed by the use of the inhibitors of poly(ADP- ribose) polymerase (PARP-1), which were able to interfere with the hydrogen peroxide induced TRPM2 activation (Reviewed in Harteneck, 2005). However, although evidence has been presented to indicate that PARP- 1 is present in mitochondria, H_2O_2 have also both been suggested to have direct effects on mitochondria (Halliwell and Gutteridge, 1999), such that the interpretation of their capacity to induce DNA damage and active PARP-1 may not be justified. In addition, PARP-1 inhibitors are known to be promiscuous within PARP family because of their structural mimicry of nicotinamide (Ferrais et al., 2003), and the concentrations required to inhibit oxidant mediated TRPM2 gating are well above those required to inhibit PARP-1 *in vitro*, precluding an unambiguous interpretation of the in cell or *in vivo* targets of these compounds. Finally, it is not obvious, at least to these authors, why PARP-1 activation should be connected to activation of a plasma membrane channel (Perraud et al., 2005).

Another group has shown H_2O_2 - induced opening of TRPM2 channel directly (Hara et al. (2002; Wehaga et al., 2002; Karft et al., 2003). Indeed, currents through TRPM2 as well as increase in free Ca^{2+} were consistently observed. In both and TRPM2- transfected HEK-293 cells, authors current responses in whole cell configuration, which also raises the possibility of a direct effect of H_2O_2 on TRPM2 channels. Experiments on COOH- terminal truncated TRPM2 channels, lacking the ADP- ribose pyrophosphatase domain, revealed a loss of ADP- ribose- mediated gating but a retention of H_2O_2 - induced activation (Wehaga et al., 2002; Karft et al.,

2003). This observation strongly supports the hypothesis of independent gating mechanisms by H₂O₂ and ADP-ribose.

According to results of current study, the H₂O₂- mediated activation of TRPM2 appears to result from a direct gating mechanism, because TRPM2 activation by H₂O₂ was relatively rapid in whole cell recordings. After adding H₂O₂ to bath, cell in whole cell records was washed by extracellular buffer and then H₂O₂ was given again. The channel was activated again by second administration of H₂O₂. From, this, we can also conclude that H₂O₂- induced, single channel activity observed in excised membrane patches is likely caused by a direct gating mechanism.

Conclusions

These results demonstrated that all three agonists, H₂O₂, ADP- ribose and NAD⁺, are capable of activating TRPM2. The three agonists are likely to interact directly with TRPM2 channels, consistent with the idea that they bind to the nudix domain (Hara et al. (2002; Wehaga et al., 2002; Karft et al., 2003). However, there remains insufficient evidence to suggest that three agonists are likely to interact directly with TRPM2 channels. Further studies including inside out and cell attached records are necessary to conclude definitively the conclusions.

Abstract

The efficient solution of a forward scattering problem is the key point in nonlinear inversion schemes associated with microwave imaging. In this paper the solution is presented for the volume integral equation based on the method of moments (MoM) and accelerated with the adaptive integral method (AIM). The proposed technique differs from the usual well-known MoM and AIM in the way the matrices are computed and stored. It is shown that the MoM matrix can be split in parts, which are independent of the material parameters of the scattering object. Then, provided with the actual values of the object parameters, the matrix is promptly restored in each iteration of the nonlinear inversion process. The coefficients of the multipole expansion of the basis functions in AIM are also computed irrespective of the object properties, so that the far-field contribution is computed on-the-fly via FFT in each iteration of the forward solution. Thus, the presented technique allows us to avoid the time-consuming procedure of the MoM matrix filling in each inversion iteration. Furthermore, the forward solution from the previous inversion iteration can be utilized in the next one as an initial guess, thus reducing the solution time for the forward model.

Introduction

Nonlinear inversion schemes applied in microwave imaging involve the solution of a forward scattering problem, which takes the major part of the overall solution time. Therefore, it is of great importance to make the forward model fast and efficient to ensure the rapid convergence of the imaging procedure.

If a single-frequency inversion technique is utilized, it implies a frequency-domain forward scattering model. The volume integral equation (VIE) technique or the finite element method (FEM) can be applied in this case. The VIE solution converges much faster than FEM [1]. However, its memory demand is also significantly higher. The FEM generates a sparse matrix, while the method of moments (MoM) applied to transform the integral equation into a system of linear equations yields a matrix with a very high fill-in. The large memory requirements of MoM for integral equations can be a bottleneck for imaging of dense inhomogeneous dielectric objects. To overcome this difficulty an accelerated MoM solver, such as the multilevel fast multipole method (MLFMM) or the adaptive integral method (AIM), can be applied.

In this paper, we present the solution for the volume integral equation by the method of moments accelerated with the adaptive integral method. The proposed technique differs from the usual well-known MoM and AIM in the way the matrices are computed and stored.

Nonlinear inversion process involves an iteration procedure, in which a forward problem is solved in each iteration with a relatively small variation of the material parameters of the object under investigation. To improve the efficiency of the algorithm the forward solution can take advantage of the solution from the previous iteration. First of all, the time consuming MoM matrix filling process can be almost eliminated if the matrix is split into parts independent of the material parameters of the scattering object. These parts can be computed only once and stored in computer memory or on a hard disk. Then, provided with the actual values of the object parameters, the matrix is promptly restored in each iteration of the nonlinear inversion process. Thus, a significant saving in the computational time can be achieved as compared to the case when the MoM matrix is

computed from scratch in each iteration. Furthermore, the forward solution from the previous inversion iteration can be utilized in the next one as an initial guess, thus reducing the solution time for the forward model.

Method of Moments for Volume Integral Equation

The volume integral equation represents the total electric field $\bar{E}(\bar{r})$ in the volume V as a sum of the incident $\bar{E}^i(\bar{r})$ and the scattered $\bar{E}^s(\bar{r})$ electric fields as

$$\bar{E}(\bar{r}) = \bar{E}^i(\bar{r}) + \bar{E}^s(\bar{r}), \quad \bar{r} \in V. \quad (1)$$

The scattered electric field $\bar{E}^s(\bar{r})$ can be written in terms of the magnetic vector potential $\bar{A}(\bar{r})$ and scalar potential $\Phi(\bar{r})$ as

$$\bar{E}^s(\bar{r}) = -j\omega\bar{A}(\bar{r}) - \nabla\Phi(\bar{r}), \quad (2a)$$

$$\bar{A}(\bar{r}) = \mu_b \int_V G(\bar{r}, \bar{r}') \bar{J}(\bar{r}') dv', \quad (2b)$$

$$\Phi(\bar{r}) = \frac{1}{\epsilon_b} \int_V G(\bar{r}, \bar{r}') \rho(\bar{r}') dv', \quad (2c)$$

where $G(\bar{r}, \bar{r}')$ is the free space Green's function and $\bar{J}(\bar{r})$, $\rho(\bar{r})$ are the unknown induced electric volume current and charge densities, respectively. In (2), ϵ_b is the permittivity and μ_b is the permeability of the background medium. It is noted that the VIE is more conveniently solved with respect to the electric flux density $\bar{D}(\bar{r})$ because its normal component is continuous across the boundary between two different dielectric materials. The substitution in variables is carried out as

$$\bar{J}(\bar{r}) = j\omega K(\bar{r}) \bar{D}(\bar{r}) = j\omega \frac{\epsilon(\bar{r}) - \epsilon_b}{\epsilon(\bar{r})} \bar{D}(\bar{r}). \quad (3)$$

To discretize the VIE in (1) the scattering object is divided into cells using curvilinear hexahedral elements. Then, the unknown function $\bar{D}(\bar{r})$ is expanded locally in each cell in terms of the higher-order hierarchical Legendre basis functions $\bar{f}_n(\bar{r})$ [2]. Finally, the Galerkin's testing is employed to transform the VIE in (1) into a system of linear equations. Assuming the dielectric permittivity $\epsilon(\bar{r})$ to be constant within each cell and taking into account that $\rho(\bar{r}) = j\omega^{-1} \nabla \cdot \bar{J}(\bar{r})$, an element z_{mn} of the resulting MoM matrix $[Z]$ can be written as

$$\begin{aligned} z_{mn} &= \frac{\langle \bar{f}_m(\bar{r}), \bar{f}_n(\bar{r}) \rangle}{\epsilon_l} + K_l \left\{ -\omega^2 \mu_b \left\langle \bar{f}_m(\bar{r}), \int_{V_l} G(\bar{r}, \bar{r}') \bar{f}_n(\bar{r}') dv' \right\rangle \right. \\ &\quad \left. - \frac{1}{\epsilon_b} \left\langle \bar{f}_m(\bar{r}), \nabla \cdot \left(\int_{V_l} G(\bar{r}, \bar{r}') [\nabla' \cdot \bar{f}_n(\bar{r}')] dv' - \int_{S_l} G(\bar{r}, \bar{r}') [\bar{f}_n(\bar{r}') \cdot d\bar{S}'] \right) \right\rangle \right\} \\ &= \frac{z'_{mn}}{\epsilon_l} + K_l z''_{mn}, \end{aligned} \quad (4)$$

where $\langle \cdot, \cdot \rangle$ is the inner product, and the subscript l denotes the cell, in which the function $\bar{f}_n(\bar{r})$ is defined. The surface integral in (4) is taken "just inside" the surface of the cell l . It is seen that both z'_{mn} and z''_{mn} are independent on the material parameters of the object. However, the expression (4) is valid only for a subset of the higher-order hierarchical Legendre basis functions $\bar{f}_n(\bar{r})$, namely those that are defined within one cell. For the basis functions that span two neighbor cells (rooftop, for instance), so that $\bar{f}_n(\bar{r}) = \bar{f}_n^-(\bar{r}) + \bar{f}_n^+(\bar{r})$, the expression (4) can be modified as

$$\begin{aligned} z_{mn} &= \frac{\langle \bar{f}_m(\bar{r}), \bar{f}_n^-(\bar{r}) \rangle}{\epsilon_l^-} + \frac{\langle \bar{f}_m(\bar{r}), \bar{f}_n^+(\bar{r}) \rangle}{\epsilon_l^+} + K_l^- z''_{mn} + K_l^+ z''_{mn} \\ &= \frac{z'^-_{mn}}{\epsilon_l^-} + \frac{z'^+_{mn}}{\epsilon_l^+} + K_l^- z''_{mn} + K_l^+ z''_{mn}. \end{aligned} \quad (5)$$

Again, the expressions for $z_{mn}^{\prime\pm}$ and $z_{mn}^{\prime\prime\pm}$ do not contain the material parameters of the scattering object. Consequently, the matrices $[Z^{\prime\prime-}]$ and $[Z^{\prime\prime+}]$ can be precomputed and stored for the subsequent iterations of the nonlinear inversion process. The first two terms in (5) do not require precomputation. They can be computed “on the fly”, since no time-consuming Green’s function calculations are involved.

Adaptive Integral Method for Volume Integral Equation

The adaptive integral method accelerates the solution of the VIE by separating elements of the MoM matrix $[Z]$ responsible for near- and far-interactions [3], as

$$[Z] = [Z^{near}] + [Z^{far}]. \quad (6)$$

The near-field elements $[Z^{near}]$ constitute a relatively small part of the full matrix. They are computed explicitly and stored in a sparse matrix format. The far interactions are accounted implicitly in the matrix-vector product $[Z^{far}][X]$, where $[X]$ is the unknown solution vector in each iteration of the iterative solution of the MoM matrix system. The following procedure makes it possible to apply the FFT to speed up the matrix-vector multiplication.

The induced volume current and charge densities are represented by point-like sources located at nodes of a regular rectangular grid enclosing the scattering object. Mathematically, it is equivalent to the expansion of the components of the functions $\overline{f_n}(\vec{r})$ and $\nabla \cdot \overline{f_n}(\vec{r})$ in terms of Dirac delta-functions as

$$f_\alpha(\vec{r}) \cong \sum_{\vec{u} \in C_\alpha} \Lambda_{\alpha\vec{u}} \delta(\vec{r} - \vec{u}), \quad (7)$$

where f_α denotes f_{nx}, f_{ny}, f_{nz} , or $\nabla \cdot \overline{f_n}$, and C_α is a cube of $(M+1)^3$ nodes. The coefficients $\Lambda_{\alpha\vec{u}}$ are chosen so that the expansion (7) reproduces the far field radiated by the current element $\overline{f_n}(\vec{r})$. This can be achieved in different ways, depending on approximation criteria established. Here, we use a multipole expansion described in [3].

To make the expansion (7) consistent with the representation (5) for the rooftop basis function, we can similarly write

$$f_\alpha(\vec{r}) = f_\alpha^-(\vec{r}) + f_\alpha^+(\vec{r}) \cong \sum_{\vec{u} \in C_\alpha^-} \Lambda_{\alpha\vec{u}}^- \delta(\vec{r} - \vec{u}) + \sum_{\vec{u} \in C_\alpha^+} \Lambda_{\alpha\vec{u}}^+ \delta(\vec{r} - \vec{u}). \quad (8)$$

Thus, the elements of the matrix $[Z^{far}]$ can be approximated as

$$z_{\beta\alpha}^{far} \cong K_l^- \sum_{\vec{v} \in C_\beta} \sum_{\vec{u} \in C_\alpha^-} \Lambda_{\beta\vec{v}} G(\vec{v} - \vec{u}) \Lambda_{\alpha\vec{u}}^- + K_l^+ \sum_{\vec{v} \in C_\beta} \sum_{\vec{u} \in C_\alpha^+} \Lambda_{\beta\vec{v}} G(\vec{v} - \vec{u}) \Lambda_{\alpha\vec{u}}^+. \quad (9)$$

In (9), we assume that constants, such as ω , ε_b , μ_b , are included in the corresponding coefficients Λ . Based on the expression (9) it can be observed that the matrix vector-product $[Z^{far}][X]$ can be effectively computed by FFT’s.

The coefficients Λ^\pm are independent of the material parameters of the scattering object, and therefore calculated once they can be reused throughout the nonlinear inversion process.

Forward Solution Procedure in the context of the Nonlinear Inversion Process

The computational procedure for the solution of the forward scattering problem in the context of the nonlinear inversion process is as follows:

1. Set initial values for the material parameters of the object under investigation.
2. Discretize the object.
3. Set the expansion order for the unknown function $\overline{D}(\vec{r})$ in each cell according to its electrical size.
4. Specify a regular rectangular grid enclosing the scattering object and compute the coefficients Λ^\pm .
5. Compute the terms $z_{mn}^{\prime\prime\pm}$ for the elements of $[Z^{near}]$ and store them in a sparse matrix format.
6. Reconstruct the matrix $[Z^{near}]$ using the precomputed $z_{mn}^{\prime\prime\pm}$ and actual material parameters of the object (Equation (5)).

3-DIMENSIONAL ITERATIVE FORWARD MODEL FOR MICROWAVE IMAGING

7. Solve the MoM matrix system using an iterative solver. The product $[Z^{far}][X]$ is calculated by FFT's in each iteration using the precomputed Λ^\pm .
8. If necessary update the material parameters of the object and return to step 6.

It should be noted that the procedure presented above is valid only for a reasonable variation of the material parameters of the object (within 10-20%). Otherwise, to avoid over- or under-discretization the procedure should be repeated starting from step 3. If our method of moments solution were based on low-order basis functions (pulse, RWG, etc.) the procedure should have been repeated starting from step 2.

Numerical Results

To verify the proposed technique, we consider scattering by a solid dielectric cube with the side length $1.4\lambda_0$. The cube is made of lossless dielectric with the relative permittivity $\epsilon_r = 4.0$, except its central slice of width $0.28\lambda_0$ (see Fig. 1). The relative permittivity of the slice is varied from $\epsilon_r = 4.1 - j0.05$ to $\epsilon_r = 5.1 - j0.55$ in 11 cycles, which represent the iterations of a nonlinear inversion process. An x-polarized plane wave illumination is considered. The object is discretized with 1000 identical cells, and the second expansion order is utilized to expand the unknown electric flux density in each cell. The discretization yields 25200 unknowns, which would require about 4.7 GB of computer memory to store the full MoM matrix. For the modified MoM and AIM techniques presented in this paper the memory requirement is 510 MB.

Fig.1. Solid dielectric cube with a central slice made of different dielectric material.

In the numerical experiments the Generalized Minimal Residual (GMRES) iterative solver with restarts after 30 iterations is employed. The time to fill the MoM matrix and the number of iterations to convergence to a relative residual error of 10^{-5} is summarized in Table 1 for all 11 cycles. In the first cycle all necessary calculations to precompute the data for the subsequent cycles are carried out, i.e., steps 1-5 of the solution procedure described in the previous section. Then steps 6-8 follow. In the subsequent cycles only steps 6-8 are involved. It is seen that a significant saving in time in cycles 2-11 is achieved by eliminating the matrix filling process and reusing precomputed result from the first cycle. The matrix reconstruction at the step 6 is extremely fast. Moreover, the number of iterations to converge is also decreased by employing as an initial guess the solution vector from the previous cycle.

Table 1. MoM matrix filling time and the number of iterations to converge.

Cycle	1(setup)	1	2	3	4	5	6	7	8	9	10	11
Permittivity	4.1-j0.05	4.1-j0.05	4.2-j0.10	4.3-j0.15	4.4-j0.20	4.5-j0.25	4.6-j0.30	4.7-j0.35	4.8-j0.40	4.9-j0.45	5.0-j0.50	5.1-j0.55
Filling time, sec	33547	15	15	15	15	15	15	15	15	15	15	15
Iterations	–	1559	1000	965	934	908	885	861	840	822	805	789

The configuration of the cycle 11 is also simulated from scratch using the classical MoM accelerated with the AIM. In Fig. 2, the obtained bistatic radar cross section (RCS) is compared to the result of the cycle 11. As expected, no difference is observed, which illustrates the correctness of the derivation and implementation of the presented technique.

Fig.2. Bistatic RCS of the dielectric cube with a central slice made of dielectric with $\epsilon_r = 5.1 - j0.55$.

Conclusions

The formulation for the classical method of moments for the volume integral equation, which is employed to solve the forward scattering problem, is modified so that the time consuming matrix filling procedure is moved to the setup phase of a nonlinear iterative inversion process. This is accomplished by splitting the MoM matrix in parts, which are independent of the material parameters of the scattering object. Once computed in the setup phase these parts are stored in the memory or on a hard disk. Then, provided with the actual values of the object material parameters, the matrix is promptly restored in each iteration of the nonlinear inversion process. Similar modifications are made in the adaptive integral method, which is applied to accelerate the MoM solution as well as to reduce its memory demands. The given numerical results show that the present technique allows the forward model to be solved fast and efficiently in each iteration of a nonlinear inversion process.

Abstract

The issue of limiting negative influence of effect of electromagnetic fields from induction heating devices using electromagnetic shields has been presented in the paper. The effectiveness of shielding for fields of different frequencies has been examined considering the material, thickness and size of shields as well as multilayer systems. The research was conducted applying computer simulation method using Flux3D and CST EM Studio programs and subsequently experimentally verified at laboratory stand. The satisfactory similarity of simulation and experimental results allows for using the simulation method in designing shields for industrial use.

Introduction

Induction as well as magnetohydrodynamic (MHD) heating devices are commonly used in industry especially in metallurgy and machine building. Conversion of energy into heat or generation of electrodynamic forces moving liquid metal happens through electromagnetic fields of low frequencies of 50 and 60 Hz, medium ones of around 30 kHz and high ones of up to around 400 kHz. Because of it the supplying sources of induction or MHD devices have negative influence on the surrounding environment. One of the technical means most often used for limiting electromagnetic radiation is electromagnetic shielding. Technical surroundings in industrial environment very frequently cause unexpected distribution of field around the devices, which makes proper design and production of effective shielding a very complicated issue. Usually adequate experience is required as well as suitable research methods need to be applied. In the authors' opinion a computer simulation method is very useful to achieve these aims provided that it is properly experimentally verified [1,2].

The multivariant calculations in the paper have been carried out applying programs using the finite elements and boundary integrals method for calculations of magnetic field intensity in front and behind the shield, since in case of induction or MHD devices these are the real risks. Different shield structures: single-layer and double-layer have also been examined taking into consideration the material they have been made from, their size and positioning in relation to the measuring point. The calculations have been performed for the frequency range most often used in induction heating and metallurgical MHD devices.

Simulation results

The simulation calculations have been made in a system (Fig.1) consisting of an inductor loaded with a charge being a field source and a shield placed between the inductor and the points in space in which the field intensity have been calculated. Flux3D computer programs were used for calculation basing on Maxwell's equations solution applying finite elements method and respectively CST EM Studio using boundary integrals method. Physical properties of materials being subject of simulation have been put into Table 1.

Shielding effectiveness has been calculated in accordance with the relation [3]:

$$S_H = 20 \lg \frac{H}{H_s}$$

where: H – magnetic field intensity in a system without a shield, H_s - magnetic field intensity in a system with a shield.

Fig.1. 3D calculation model for simulation of shielding effectiveness of induction devices

The influence of the shield's material, its thickness, structure, existence of one or two layers and the placing between source and a measuring point on shielding effectiveness has been examined with certain supplying parameters. The simulation results are shown in Figures 2-5.

Fig. 2. Effect of using shield on magnetic induction value on measuring path outside shield

Using an electromagnetic shield (Fig.2) leads to a rapid four times decrease of magnetic induction value in places outside the shield especially in its nearest proximity, since with moving away from the source the field weakens in a natural way.

Fig.3. Calculated magnetic induction values for shields made of various materials

The materials of high conductivity and possibly of high magnetic permeability (ferromagnetics) have the best shielding properties (Fig.3) by certain shield thickness. One has to however bear in mind that using ferromagnetics as shields is limited and near the sources with medium and high frequencies even impossible due to their quick heating leading to melting in places. While choosing the material its costs also have to be considered. This makes using of copper very problematic and therefore aluminum and non-magnetic steel are used far more often

Tab. 1. Physical properties of materials

Material	Conductivity, MS/m	Magnetic permeability
Aluminum	33	1
Brass	25	1
Steel	4,3	1000
Copper	55	1

Figure 4 indicates that the shield should not be too thin (0,5 mm) in relation to the depth of electromagnetic field penetration

$$\delta = \sqrt{\frac{2}{\mu\gamma\omega}}, \text{ where } \mu - \text{magnetic permeability of the shield, } \gamma - \text{electrical conductivity of the shield, } \omega -$$

pulsation of the coil current ($\omega = 2\pi f$). Nevertheless further increase of its thickness to over 2 mm is purposeless since the production costs grow significantly with slight decrease of induction value.

On the other hand the course of curves shown in Figure 5 indicates that application of double-layer structures (two different materials) is reasonable only for a system conductor (Cu or Al) – ferromagnetic. It seems that this has to be subject of further research.

Fig.4. Calculated values of magnetic induction for aluminum shields of various thicknesses

Fig. 5. Calculated values of magnetic induction for double-layer shields in relation to single-layer shield made of copper with same thickness as double-layer shields

Experimental verification

The carried out simulation research was experimentally verified in the laboratory of Electromagnetic Risks Workroom in the Central Institute of Work Protection. The examinations have been performed in the system as in Figure 6 and covered determination of frequency characteristics of shielding effectiveness for metal shielding structures, comprising of various combinations of sheet metal. The frequency characteristics have been determined for electromagnetic fields' frequency of 20 to 100 kHz. The Helmholtz's coils were used as electromagnetic field source during examinations. The supplying system consisted of a HAMEG HM8130 generator, PA-300S power supplier, H/PA-300S adjusting system. The stability of the generated magnetic field

USING COMPUTER PROGRAMS TO EVALUATE SHIELDS

was monitored with excitation check using HP 34401A voltmeter. The shielding effectiveness was determined on the basis of magnetic induction measurements using Narda ELT-400 meter (S/N K-0036) with 1Hz-400kHz probe (S/N K-0042), applied in a RMS 320 μ T, LowCut 1Hz working mode. Comparison of shielding effectiveness results obtained from simulation and measurements has been shown in Figure 7 and 8.

Fig.6. Measuring system for experimental verification of shielding effectiveness

Fig.7. Comparison of shielding effectiveness results obtained from simulation (Flux3D, CST Studio) and measurements for shield made of sheet copper of 1 mm thickness

The presented comparison show that the calculation carried out using Flux3D program for medium and high frequencies > 750 Hz are very similar to experimental results (Fig.7) for single-layer shield and a little less so for

double-layer shield (Fig.8). In both cases good conformity of CST Studio and experimental results has been obtained for low frequencies < 250 Hz.

Fig.8. Comparison of shielding effectiveness results obtained from simulation (Flux3D, CST Studio) and measurements for double-layer shield made of sheet copper of 1 mm thickness and made of brass of 1 mm thickness

Summary

Usability of computer simulation method for research on shielding effectiveness and consequently on limitation of electromagnetic radiation levels around induction devices has been presented in the paper. The carried out examinations proved that for frequency ranges applied in induction heating the best results of shielding effectiveness were obtained for copper shields of thicknesses up to 2 mm. Only slightly worse results were obtained for aluminum, but considering the cost of both materials, the latter will be much more frequently used. Interesting results have been obtained for double-layer systems especially for aluminum-steel, however this requires further research in order to select the optimum sort of sheet steel and thickness of both layers.

Application of computer simulation may be a basic tool in the design process of electromagnetic shields in industry installations.

Abstract

C95.1-2005 “IEEE Standard for Safety Levels with Respect to Human Exposure to Radio Frequency Electromagnetic Fields, 3 kHz to 300 GHz” was approved on October 5, 2005 and published on April 19, 2006. This revision (of C95.1-1991) is based on an evaluation of the scientific literature through 2003. The recommendations are intended to protect people of all ages against established RF adverse health effects. Major changes (compared with the 1991 standard) are: 1) The maximum permissible exposure values of the lower tier are harmonized with other standards between 30 MHz and 100 GHz. 2) The upper frequency for the basic restriction on whole-body averaged SAR has been reduced from 6 to 3 GHz. 3) The BRs on peak spatial-average SAR have been changed from 1.6 W/kg and 8 W/kg for the lower and upper tiers to 2 W/kg and 10 W/kg, respectively, and the corresponding averaging mass from 1 to 10 g of tissue in the shape of a cube. For the extremities (including forearms and lower legs) and pinnae, the permitted peak SAR averaged over 10 g of tissue is now 20 W/kg for the upper tier and 4 W/kg for the lower tier. 4) The averaging times for both the upper and lower tiers have been changed to more realistic values for frequencies above 3 GHz.

Introduction

The purpose of IEEE Std. C95.1-2005 [1] is to provide exposure limits (basic restrictions and derived limits) to protect against established adverse effects to human health associated with exposure to RF electric, magnetic and electromagnetic fields over the frequency range of 3 kHz to 300 GHz. This standard is a revision of IEEE Std C95.1-1991 (1999 edition) [2] and IEEE Std C95.1b-2004 [3]. In revising the standard, findings of studies published between 1950 and December 2003¹ were considered, including those studies that involve low level exposures where increases in temperature could not be measured or were not expected. New insights gained from improved experimental and numerical methods and a better understanding of the effects of acute and chronic RF electromagnetic field exposures of animals and humans are included. A lack of credible scientific and medical reports showing adverse health effects for RF exposures at or below corresponding exposure limits in past standards supports the protective nature of the standards. This standard for the first time includes guidance on the necessity of an RF exposure control program (C95.7-2005) [4].

Below 100 kHz, the effect being minimized is aversive or painful electrostimulation. Above 100 kHz there can be a sensation of heating, which is not considered adverse. The limits in this standard may not prevent such

¹ Although the literature cutoff date was December 2003, several papers published in 2004 and 2005 were included.

thermal sensations; they are designed to protect against adverse health effects resulting from tissue heating, the only established mechanism relating to adverse effects of exposure to RF energy at frequencies above 100 kHz.

The standard consists of two main parts. The normative part includes an overview of the document (scope, purpose, and introduction), references, definitions, and recommendations. The informative part is comprised of 7 Annexes, with the first three explaining the revision process, summary of literature, and rationale of the revision. Examples of practical applications are shown in Annex D. The last three annexes are glossary, literature database (with 1143 references) and bibliography. This paper summarizes the 250 page standard, with emphasis on the new features. For details, especially on the literature summary of about 1300 peer reviewed papers (Annex B) and rationale of all changes (Annex C), please refer to the original standard [1].

Recommendations

The recommendations are expressed in terms of basic restrictions (BRs) and maximum permissible exposure (MPE) values (sometimes called reference levels, or investigation levels). The BRs are limits on internal fields, specific absorption rate (SAR), and current density; the MPEs, which are derived from the BRs, are limits on external fields and induced and contact current. The recommendations, which protect against effects associated with electrostimulation and tissue and whole body heating, are intended to apply to all human exposures except for exposure of patients by, or under the direction of, physicians and medical professionals.

BRs and MPEs for frequencies between 3 kHz and 100 kHz

Table 1 lists basic restrictions for particular areas of the body in terms of the electric field within the biological tissue (*in situ*). Two parameters are listed in the table: the rheobase *in situ* field, E_0 , and a strength-frequency parameter, f_e . Limits are determined from Table 1 as:

$$E_i = E_0 \text{ for } f \leq f_e$$

$$E_i = E_0 (f/f_e) \text{ for } f \geq f_e$$

Where E_i is the maximum allowed induced *in situ* electric field.

Table 1 – BRs applying to various regions of the body

		Action Level ^a	Persons in Controlled Environments
Exposed tissue	f_e (Hz)	E_0 (rms) (V/m)	E_0 (rms) (V/m)
Brain	20	5.89×10^{-3}	1.77×10^{-2}
Heart	167	0.943	0.943
Extremities	3350	2.10	2.10
Other tissues	3350	0.701	2.10

^a Within this frequency range the term “action level” is equivalent to the term “general public”.

Table 2 lists the MPEs for the magnetic field (flux density, B , and magnetic field strength, H) for exposure of the head and torso. The averaging time for an rms measurement is 0.2 second.

Table 2 – MPE for exposure of head and torso: $f = 3$ kHz to 5 MHz

Frequency range (kHz)	Action Level		Persons in Controlled Environments	
	B_{rms} (mT)	H_{rms} (A/m)	B_{rms} (mT)	H_{rms} (A/m)
3.0 – 3.35	$0.687/f$	$547/f$	$2.06/f$	$1640/f$
3.35 – 5000	0.205	163	0.615	490
NOTE— f is expressed in kHz.				

The MPEs for the limbs (entire arms and legs) are listed in Table 3.

Table 3 – MPE for the limbs: $f = 3$ kHz to 5 MHz

Frequency range (kHz)	Action Level		Persons in Controlled Environments	
	B_{rms} (mT)	H_{rms} (A/m)	B_{rms} (Mt)	H_{rms} (A/m)
3.0 – 3.35	$3.79/f$	$3016/f$	$3.79/f$	$3016/f$
3.35 – 5000	1.13	900	1.13	900
NOTE— f is expressed in kHz.				

Table 4 lists MPEs in terms of the undisturbed (absent a person) external electric field, E .

Table 4 – Electric field MPE – whole body exposure: $f = 3$ kHz to 100 kHz

	Action Level	Persons in Controlled Environments
Frequency range (kHz)	E (rms) (V/m)	E (rms) (V/m)
3 kHz to 100 kHz	614	1842

The limits in Table 5 protect against adverse electrostimulation effects.

**Table 5 – RMS induced and contact current limits for continuous sinusoidal waveforms,
 $f = 3 \text{ kHz to } 100 \text{ kHz}$**

Condition	Action Level (mA)	Persons in Controlled Environments (mA)
Both feet	$0.90f$	$2.00f$
Each foot	$0.45f$	$1.00f$
Contact, grasp ^a	--	$1.00f$
Contact, touch	$0.167f$	$0.50f$
NOTE 1— f is expressed in kHz.		
NOTE 2—Limits apply to current flowing between the body and a grounded object that may be contacted by the person.		
NOTE 3—The averaging time for determination of compliance is 0.2 s.		

^a The grasping contact limit pertains to controlled environments where personnel are trained to make grasping contact and to avoid touch contacts with conductive objects that present the possibility of painful contact.

BRs and MPEs for frequencies between 100 kHz and 3 GHz

The whole-body-average BRs shown in Table 6 are based on established adverse health effects associated with heating of the body during whole-body exposure. Consistent with the approach used in the prior standard to derive exposure limits, a traditional safety factor of ten (10) has been applied to the established SAR threshold for such effects, yielding an SAR of 0.4 W/kg averaged over the whole body. In the absence of an RF safety program, the BRs of the lower tier (action level) may also be used for the general public. Applied to members of the general public, the lower tier provides more assurance that continuous, long-term exposure of all individuals in the population, will be without risk of adverse effects. The localized exposure BRs shown in Table 6 are established to protect against excessive temperature rise in any part of the body that might result from localized or non-uniform exposure. When averaging SAR over a 10-g volume of tissue in the extremities and the pinnae, only SAR values for that tissue may be considered. If any cubic volume contains tissue from both the body and the extremities or pinna, each must be considered separately.

Table 6 – BRs for frequencies between 100 kHz and 3 GHz

	Action Level ^a SAR ^b (W/kg)	Persons in Controlled Environments SAR ^c (W/kg)
Whole-body exposure (Whole-Body Average— WBA)	0.08	0.4
Localized exposure (Local peak spatial-average)	2 ^c	10 ^c
Localized exposure (Extremities ^d and pinnae)	4 ^c	20 ^c

^a BR for the general public when an RF safety program is unavailable.

^b SAR is averaged over the appropriate averaging times as shown in Table 8 and Table 9.

^c Averaged over any 10 g of tissue (defined as a tissue volume in the shape of a cube)².

^d The extremities are the arms and legs distal from the elbows and knees, respectively.

² The volume of the cube is approximately 10 cm³.

Contact and induced current limits, 100 kHz to 110 MHz

In the transition region of 100 kHz to 5 MHz, two sets of contact and induced current limits apply. The limits in Table 5 protect against effects associated with electrostimulation and the limits in Table 7 protect against effects associated with tissue heating. Contact and induced current shall both be limited as specified in Table 7.

**Table 7 – RMS induced and contact current limits for continuous sinusoidal waveforms,
 $f = 100 \text{ kHz to } 110 \text{ MHz}$**

Condition	Action Level ^a (mA)	Persons in Controlled Environments (mA)
Both feet	90	200
Each foot	45	100
Contact, grasp ^b	-	100
Contact, touch	16.7	50
NOTE 1—Limits apply to current flowing between the body and a grounded object that may be contacted by the person.		
NOTE 2—The averaging time for determination of compliance is 6 minutes.		

^a MPE for the general public in absence of an RF safety program.

^b Grasping contact limit pertains to controlled environments where personnel are trained to make grasping contact and to avoid touch contacts with conductive objects that present the possibility of painful contact

BRs for frequencies between 3 GHz and 300 GHz

BRs to protect against adverse effects associated with heating are established for incident power density for frequencies between 3 GHz and 300 GHz. Such restrictions are derived with consideration of adverse effects thresholds (based on the literature review and evaluation), their distribution among the population, and safety factors. The BRs for frequencies between 3 GHz and 300 GHz are the same as the corresponding MPEs shown in Table 8 and Table 9, and are considered appropriate for all human exposure.

Table 8 – MPE for the upper tier (people in controlled environments)

Frequency range (MHz)	RMS electric field strength (E) ^a (V/m)	RMS magnetic field strength (H) ^a (A/m)	RMS power density (S) E-field, H-field (W/m ²)	Averaging time $ E ^2$, $ H ^2$ or S (min)
0.1–1.0	1842	$16.3 / f_M$	$(9000, 100\,000 / f_M^2)^b$	6
1.0–30	$1842 / f_M$	$16.3 / f_M$	$(9000 / f_M^2, 100\,000 / f_M^2)$	6
30–100	61.4	$16.3 / f_M$	$(10, 100\,000 / f_M^2)$	6
100–300	61.4	0.163	10	6
300–3000	—	—	$f_M / 30$	6
3000–30 000	—	—	100	$19.63 / f_G^{1.079}$
30 000–300 000	—	—	100	$2.524 / f_G^{0.476}$
NOTE— f_M is the frequency in MHz, f_G is the frequency in GHz.				

^a For exposures that are uniform over the dimensions of the body, such as certain far-field plane-wave exposures, the exposure field strengths and power densities are compared with the MPEs in the Table. For non-uniform exposures, the mean values of the exposure fields, as obtained by spatially averaging the squares of the field strengths or averaging the power densities over an area equivalent to the vertical cross section of the human body (projected area), are compared with the MPEs in the Table.

^b These plane-wave equivalent power density values are commonly used as a convenient comparison with MPEs at higher frequencies and are displayed on some instruments in use.

Table 9 – Action level (MPE for the general public when an RF safety program is unavailable)

Frequency range (MHz)	RMS electric field strength (E) ^a (V/m)	RMS magnetic field strength (H) ^a (A/m)	RMS power density (S) E-field, H-field (W/m ²)	Averaging time $ E ^2$, $ H ^2$ or S ^b (min)	
0.1–1.34	614	16.3 / f_M	(1000, 100 000 / f_M^2) ^c	6	6
1.34–3	823.8 / f_M	16.3 / f_M	(1800/ f_M^2 , 100 000 / f_M^2)	f_M^2 / 0.3	6
3–30	823.8 / f_M	16.3 / f_M	(1800/ f_M^2 , 100 000 / f_M^2)	30	6
30–100	27.5	158.3 / $f_M^{1.668}$	(2, 9 400 000 / $f_M^{3.336}$)	30	0.0636 $f_M^{1.337}$
100–400	27.5	0.0729	2	30	30
400–2000	—	—	f_M / 200	30	
2000–5000	—	—	10	30	
5000-30 000	—	—	10	150 / f_G	
30 000-100 000	—	—	10	25.24 / $f_G^{0.476}$	
100 000-300 000	—	—	(90 f_G -7000)/200	5048/[(9 f_G -700) $f_G^{0.476}$]	
NOTE— f_M is the frequency in MHz, f_G is the frequency in GHz.					

^a For exposures that are uniform over the dimensions of the body, such as certain far-field plane-wave exposures, the exposure field strengths and power densities are compared with the MPEs in the Table. For non-uniform exposures, the mean values of the exposure fields, as obtained by spatially averaging the squares of the field strengths or averaging the power densities over an area equivalent to the vertical cross section of the human body (projected area), are compared with the MPEs in the Table.

^b The left column is the averaging time for $|E|^2$, the right column is the averaging time for $|H|^2$. For frequencies greater than 400 MHz, the averaging time is for power density S.

^c These plane-wave equivalent power density values are commonly used as a convenient comparison with MPEs at higher frequencies and are displayed on some instruments in use.

RF safety programs

Throughout the RF spectrum applicable to this standard, the MPEs apply to exposure of people, i.e., compliance with this standard is determined by whether or not exposures of people to RF fields, currents and voltages exceed the applicable MPEs. Where there may be access to RF fields, currents, and/or voltages that exceed the lower tier (Action Level) of this standard, an RF safety program such as detailed in IEEE Std C95.7-2005 [4] shall be implemented to ensure that exposures do not exceed the MPEs or BRs for persons in a controlled environment.

Similarities and differences between this standard and IEEE Std C95.1-1991

Similarities:

- a) All relevant reported biological effects at either low (“non-thermal”) or high (“thermal”) levels were evaluated. Research on the effects of chronic exposure and speculations on the biological significance of low-level interactions have not changed the scientific basis of the adverse effect level.
- b) WBA and peak spatial-average SAR remain the basic restrictions of exposure over much of the RF spectrum. The whole body average SAR values remain the same as in IEEE Std C95.1-1991, i.e., 0.4 and 0.08 W/kg.
- c) The MPE for exposures in controlled environments remain the same as in IEEE Std C95.1-1991.
- d) The averaging time remains six minutes for frequencies below 3 GHz for effects associated with tissue heating. For electrostimulation effects, the averaging time is 0.2 s for an rms measurement. Peak electrostimulation limits apply to instantaneous values within the applicable bandwidth.

Differences:

- a) IEEE Std C95.1-1991 contains two tiers; an upper tier for “exposures in controlled environments” and a lower tier for “exposures in uncontrolled environments.” In this standard, two tiers have also been set. As in the 1991 standard, an upper tier has been set for exposure of persons in controlled environments. While the weight of scientific evidence supports the conclusion that no measurable risk is associated with RF exposures less than the upper tier of this standard, it is impossible to scientifically prove absolute safety (the null hypothesis). Thus a lower tier has been set with an extra margin of safety that applies to all other individuals. The lower tier, called an “action level,” recognizes public concerns, takes into account uncertainties in laboratory data and in exposure assessment, and supports the process of harmonization with other standards, e.g., the NCRP recommendations [6] and the ICNIRP guidelines [7]. For practical purposes, the lower tier may be used for the general public or as an action level, above which an RF safety program shall be implemented to protect against exposures that exceed the upper tier.
- b) The upper frequency boundary over which whole body average SAR is deemed to be the basic restriction has been reduced from 6 GHz to 3 GHz.
- c) The long-term MPEs for the lower tier are different from those in IEEE Std C95.1-1991 and are in general more restrictive between 300 MHz and 300 GHz.
- d) The peak spatial-average SAR values have been changed from 1.6 W/kg and 8 W/kg for lower and upper tiers to 2 W/kg and 10 W/kg, respectively.
- e) The averaging mass for determining the peak spatial-average SAR has been changed from 1 g of tissue in the shape of a cube to 10 g of tissue in the shape of a cube.
- f) Although implicit in previous versions of IEEE Std C95.1, the present standard explicitly relies on “basic restrictions”.
- g) The standard now requires the development and implementation of an RF safety program in controlled environments.
- h) The averaging time for both the upper and lower tiers has been changed for frequencies above 3 GHz.
- i) The upper frequency at which maximum induced and contact currents are specified is now 110 MHz compared with 100 MHz in the previous standard.
- j) The frequency at which the upward ramp begins for the relaxation of the power density limits for localized exposure has been changed from 6 GHz to 3 GHz.
- k) In recognition of the differing impact of exposure to particular frequencies, the standard provides sections devoted to three frequency bands: 3 kHz to 5 MHz, 100 kHz to 3 GHz and 3 GHz to 300 GHz. The limits in the first band minimize adverse effects associated with electrostimulation. This overlaps the second band where the limits also protect against effects associated with heating. The limits in the third band protect against effects associated with heating. Differences within each of those bands are provided below.

Features:

- a) **3 kHz to 5 MHz** – The standard defines basic restrictions (BR) in terms of the *in situ* (within biological tissue) electric fields for different regions of the body. Magnetic field MPEs are specified for the arms and legs and for the head and torso, but compliance with the standard can be demonstrated for uniform sinusoidal magnetic fields by showing that either the *in situ* electric field BR or the magnetic field MPE is satisfied. If the magnetic field is not constant over the head and torso, it is sufficient to demonstrate that the basic restrictions are satisfied, or that the spatial peak of the magnetic field MPE is not exceeded. Based on current knowledge of adverse effects on humans within this frequency range, the whole body electric field MPE for the controlled environment has been increased. Similarly, the magnetic field MPEs, with separate requirements for body portions as noted above, have been increased for both the general public and controlled environments and have been made frequency dependent. Averaging time for an RMS measurement is 0.2 second. Formulas have been included for determining maximum permitted peak electric fields for both *in situ* and environmental considerations.
- b) **100 kHz to 3 GHz** – In this frequency range where SAR is the controlling criterion, the revised standard confirms the presumed threshold whole body average SAR of 4 W/kg for potentially adverse effects. Localized exposure restriction criteria (peak spatial-average SAR) have been changed for both the upper and lower tiers. Peak spatial average SAR for any body tissue including the hands, wrists, forearms, feet, ankles, lower legs and pinnae, is required to be determined over 10 g of tissue in the shape of a cube. Peak spatial average SAR for the 10-g sample is to be no greater than 10 W/kg for the upper tier and 2 W/kg for the lower tier. For the hands, wrists, forearms, feet, ankles, lower legs and pinnae, the permitted peak spatial average remains as specified previously in 10 g of tissue, *i.e.*, 20 W/kg for the upper tier and 4 W/kg for the lower tier. The contact current limits for the frequency range of 100 kHz to 110 MHz have been subdivided into touch and grasping conditions, with the grasping condition confined to the controlled environment. The permissible touch contact current has been reduced for both the controlled environment and the general public. The lower part of this frequency range, *i.e.*, 100 kHz to 5 MHz, is a transition region where the limits protecting against electrostimulation and the limits protecting against effects associated with heating must be met.
- c) **3 GHz to 300 GHz** – In this frequency range, the interactions become quasi-optical, and the MPEs are expressed in terms of incident power density and exposure duration. The principal change in the standard has been in the MPE frequency dependence above 300 MHz for the lower tier (general public).

Summary

IEEE C95.1-2005 provides recommendations to protect against established adverse effects in human beings exposed to electromagnetic fields in the frequency range from 3 kHz to 300 GHz. Similarities and differences from the IEEE C95.1-1991 (and its two amendments) are discussed. A notable revision to the new standard is the recommendation of peak spatial average SAR of 2 and 10 W/kg averaged over 10 g tissue for the lower and upper tier limits, respectively. This revision resolves a major harmonization issue with other RF standards and guidelines. Cooperative efforts should be continued to achieve internationally harmonized exposure limits.

EXPERIMENTAL DOSIMETRY FOR THE UK MOBILE TELECOMMUNICATIONS AND HEALTH RESEARCH PROGRAMME

BENJAMIN LOADER
NATIONAL PHYSICAL LABORATORY,
HAMPTON ROAD, TEDDINGTON MIDDLESEX, UK, TW11 0LW

Abstract

This paper presents a review of the dosimetry in the UK Mobile Telecommunications and Health Research (MTHR) programme. It describes the exposure systems used in the human volunteer studies, their output characteristics, and the rationale behind their specifications. It also describes how traceability to national standards was established for the *in vitro* studies. Problems encountered during the development of these systems are also presented.

Introduction

The Link Mobile Telecommunications and Health Research Programme (MTHR) resulted from the publication of the report by the Independent Expert Group on Mobile Phones [1]. The MTHR has funded research in the UK to a value of £8.8 million to investigate the impact of mobile telecommunications on health. In determining the research priorities, the programme has sought to take into account public concerns about mobile communications technology as well as other research conducted nationally and internationally. To date, MTHR has funded twenty projects, and another six projects have been funded as an adjunct to the programme by the UK Department for Trade and Industry or the Home Office. Effective and accurate dosimetry is essential if meaningful conclusions are to be drawn from these studies. Under the programme, the National Physical Laboratory (NPL) has provided dosimetry support to the research projects. This support has included advice regarding the specification of exposure systems, independent verification that the systems used meet these specifications, and calibration to provide traceability to National Standards. Staff at NPL have also measured and characterised other aspects of the systems' performance, such as the low frequency magnetic fields that they emit [2].

For dosimetry purposes, the studies fall into the following categories: human volunteer studies on handset exposure, human volunteer studies on base station exposure, *in vitro* studies, *in vivo* studies, and epidemiology. This paper considers the exposure systems used for the human volunteer and *in vitro* studies. It provides a description of the devices used for generating the exposures, the rationale behind the choice of signal characteristics and exposure levels, and problems that were encountered during their development. The paper also examines how traceability to National Standards was established for exposures in the *in vitro* studies, and how the systems were characterised at NPL.

1. Human-volunteer studies

Handset exposure. During typical phone use there is a wide variation in exposure. This is dependent on the phone type, radio reception conditions, pattern of speech or type of data sent, the way the phone is held, and whether it is used in the left or right hand. Along with the RF signals, the phone will generate low frequency magnetic fields caused by the pulsed nature of the battery currents and static magnetic fields caused by the earpiece in the phone. Movement of the phone may modulate such static fields during use. There will be some heating of the skin in the region of the phone because the circuits dissipate heat and the use of the phone may also affect the subject's posture. All of these factors could potentially affect the outcomes of human volunteer studies. It would be impossible to encompass all possible variations in exposure conditions within a single experiment. Practical considerations limit the duration of test sessions for human volunteer studies, and therefore the number of exposure conditions that can be tested. Whilst a system could be designed to generate uniform exposure to cover all possible regions exposed during phone use, such a system would not give realistic patterns of exposure, and in particular, any effects due to the field gradients in the head would not be apparent.

MCL (www.mcluk.org), in collaboration with the Department of Electronics at York University, developed the handsets that were used for all the human volunteer studies on handset exposure within the MTHR programme (Fig. 1). These handsets are designed to give accurate and reproducible exposures representative of those from GSM [3] or TETRA [4] phones, and to facilitate double-blind experiments. The handsets are battery powered, to allow free movement of the subjects during the tests and also to avoid coupling effects that occur if a cable connects the antenna to the signal source. They can operate for approximately one hour before the batteries need

EXPERIMENTAL DOSIMETRY FOR THE UK MTHR PROGRAM

charging and there is an audible low battery warning. They operate as “stand alone” transmitters without the requirement for an operational network.

Three modes of exposure were used for the MTHR studies; pulsed mode (GSM or TETRA), continuous wave (CW) mode, which produces an unmodulated signal with the same frequency and average power as the pulsed mode, and sham mode. CW mode was included to determine whether any observed effects are due to the pulsed nature of mobile phone signals. Selection of the mode of operation is by two 16-position rotary switches, the codes for each mode being assigned randomly for each handset and held by the manufacturer. This facilitates double blind experiments. The characteristics of the output from the handsets in each mode are shown in Table 1.

Figure 1: Picture of the MTHR handsets. Front and rear view. The antenna is angled slightly towards the head to increase specific absorption rate (SAR) level. Visible are two rotary mode switches and RF test connector used to check correct operation prior to test sessions.

Table 1: Comparison of exposure modes.

Output characteristics	GSM or TETRA	Mode CW	Sham
RF exposure level	1.4 Wkg ⁻¹	1.4 Wkg ⁻¹	0.002 Wkg ⁻¹
Pulse modulation of signals	Yes	No	No
Low frequency magnetic fields	Yes	No	No
Static magnetic field	Yes	Yes	Yes
Heat dissipation from circuits in phone	Yes	Yes	Yes

The characteristics of the modulation for the GSM and TETRA modes are given in Table 2. The transmission frequency was chosen to be 888 MHz for the GSM handset and 381 MHz for the TETRA phone. The GSM handset frequency is just outside the normal operating band of the GSM system, and this is to avoid interference with operational networks. Signal modulation gives rise to a low frequency magnetic field, which is the case for a real phone, and these are shown in Fig. 2. In the sham mode, the CW signal is generated and a switch diverts the signal to an internal load so that the antenna does not transmit it. This gives the same battery life and operating temperature as the transmitting modes, which is a requirement for double blinding. The sham mode therefore produces the same static magnetic field as the CW mode. The circuit boards within the handset also radiate electromagnetic fields in the sham mode and this, rather than the performance of the RF switch used, limits the degree of isolation that can be achieved. In the “sham” mode the exposure level is reduced by at least 20 dB compared to the exposed modes. The field level in air at 10 cm from the handset is between 0.5 Vm⁻¹ and 1 Vm⁻¹ for the sham mode, compared to 13 V/m for the CW exposed mode.

Table 2: Main characteristics of GSM & TETRA signals.

GSM		TETRA	
Handset characteristics	Included in MTHR handset	Handset characteristics	Included in MTHR handset
GSM 900	Yes	Voice plus data mode (V + D)	Yes ²
GSM 1800	No	Direct mode (DMO)	No
GSMK mask for pulse shape (GSM)	Yes	Packet data optimised mode (PDO)	No
PSK modulation (GSM)	Yes	DQPSK modulation ³	Yes
Super- and Hyper-frame structures.	Yes	Hyper and Multi-frame structure	Yes
Variation in slot transmit power (adaptive power control)	No	Variation in slot transmit power (adaptive power control)	No
GSM DTX mode ¹	No ¹	Correct pulse shape	Yes
Frequency hopping	No	Frequency hopping	No
Multi-slot operation	No	Multi-slot operation	No

Notes:

1. The handsets have this capability, but it was not used for the MTHR trials. Discontinuous Transmission (DXT) mode will alter the low frequency magnetic fields produced by the handset.
2. V + D is the most common mode of operation for TETRA. Only voice communication is included.
3. DQPSK = $\pi/4$ Differential Quaternary Phase Shift Keying.

Figure 2. Magnetic field from MTHR handsets in GSM and TETRA “exposed” mode [2].

SAR is the specific absorption rate of RF energy in tissues in watts per kilogram (Wkg^{-1}). The target level for the GSM, CW and TETRA exposures was chosen as 1.4 Wkg^{-1} averaged over a 10 g mass. This is the highest level that ensures volunteers will not be exposed above the ICNIRP limit of 2 Wkg^{-1} for public exposure, allowing for the uncertainty of the dosimetry. Most available GSM handsets are designed to comply with IEEE limit [5] of 1.6 Wkg^{-1} averaged over a 10 g mass, so this level is representative of GSM phones. TETRA handsets with 1 W peak power produce similar SAR levels to GSM phones when used in voice communication mode [6, 7]. However, TETRA handsets having 3 W peak power can produce higher SAR levels [7]. The SAR from each handset was measured to an accuracy of $\pm 30\%$ by an accredited test laboratory and was checked and adjusted periodically during the studies. The handsets incorporate a test mode that allows the modulated or CW signal to be measured with a power meter prior to each test session, to confirm that the handset is operating correctly. Fig. 3 shows the measured SAR distribution from the GSM handset. The 10 g averaged SAR from the antenna is 1.4 Wkg^{-1} . The 10 g averaged SAR in the region of the body of the handset is 0.4 Wkg^{-1} .

Figure 3. SAR distributions from the MTHR GSM handset (reproduced courtesy MCL Ltd). (a) Position of the handset for left hand exposures. (b) SAR distribution from antenna. (c) SAR distribution from circuits in the handset.

Both left hand and right hand use of the phone were considered in the studies. The phone was positioned in the “cheek position” defined in [8] when used on the left-hand side of the head. When used on the right-hand side of the head, it was shifted upwards from this position by 4 cm. This ensures that the position of the maximum SAR relative to the ear remains the same for both sides of the head, even though the antenna is not located symmetrically on the handset. The region of brain exposed may affect whether a particular effect is detected.

From switch on to the point the low battery audible warning activates, there is a gradual reduction in the power radiated by the handset, as shown in Fig. 4. Note that during all sessions, the handsets are switched on three minutes prior to beginning the tests.

Figure 4. Change in radiated power versus time from switch on. (a) GSM handset, (b) TETRA handset

Achieving double blinding for the handsets was quite challenging. Each mode of operation must discharge the battery at the same rate, must result in the same degree of heating of the handset, and produce no audible or visual indications. Initial trials of the handsets showed that they got hotter in CW mode than modulated mode, and subjects were able to detect this difference. Adding an additional resistor to generate heat in the pulsed mode rectified this, but meant the handsets may get slightly hotter than is the case for a normal phone. In very quiet environments, some subjects were able to hear a clicking noise from the battery when the handset was in pulsed modes. Some low-level background noise was necessary to mask this sound during the experiments.

Studies look for differences in a measurable response resulting from the different exposure modes. Given the nature of the three exposure conditions from the MTHR handsets, studies using the handsets would show:

1. *Effects that are due to GSM or TETRA signals from the handset in the presence of static magnetic fields, low frequency magnetic fields and contact heating that is typical of a real phone.*
2. *Effects arising from a CW signal whose severity increase with exposure level.*

However, the following are not tested, since these are present in both the exposed and sham conditions:

1. *Effects due to CW signals with a threshold that is below the sham level and whose severity does not increase with exposure level.*
2. *An effect arising solely from the static magnetic field of the handset.*
3. *Effects caused solely by the very slight heating of the head that occurs through contact with the warm phone.*

Base Station exposure. Base stations may have multiple traffic and control channels. The control channels always have full slot occupancy and maximum power level. The traffic channels have variable slot occupancy, and some designs have variable power level for the bursts (down-link power control). The inter-slot guard period that separates bursts are synchronised between channels. In real-life situations, the signal is reflected and attenuated by buildings and structures. As a person moves through the field, the amplitude of the signal may increase and decrease (fading multi-path). They will be exposed to many different radio signals simultaneously. The height of the antenna and the elevation pattern mean exposure may not decrease with distance from the antenna. Base stations may generate electromagnetic fields other than the transmitted signals, but these emissions are limited by the GSM specifications [3].

The base station exposure system used by MTHR was developed by Red-M Ltd [9], and installed at the University of Essex in an absorber-lined screened room supplied by NPL. The system provides three exposure modes; GSM mode, UMTS mode and sham mode. The sequence of exposure for each test session is determined by a test code that is assigned to each volunteer in the study, and these are randomised. This facilitates double blinding of the studies. In addition there is an open provocation mode. Fading multi-path effects were not simulated in the exposure system. Whilst fading multi-path simulators to represent different environments are available, this would have added considerably to the cost of the exposure system, and the choice of which environment to simulate would be difficult. The system uses a Rhode and Schwarz SMU 200A digital signal generator. For GSM mode, the amplitude-quadrature (I/Q) data of the traffic and control channels is generated externally and sent to the modulation inputs of the signal generator. An external circuit then adds the inter-slot guard period to give the correct pulse shape. As a result the data sent is not synchronised to the bursts. For UMTS, the signal generator generates the signal internally. In the sham mode the modulation and RF output

from the signal generator are turned off. The signals are amplified before being transmitted by a vertically polarised log periodic dipole array (LPDA) located inside the screened room. The antenna is at a distance of 5 m from the subject and is concealed behind a curtain. Forward and reverse power to the antenna are monitored prior to test sessions to confirm correct operation of the system. To reduce the field level that is present in the sham mode, the signal generator and amplifier are located outside the screened room used for the exposures. The system is calibrated every six months during the study to ensure that its output remains stable.

The total power density in the GSM mode and also the UMTS signal is $10 \text{ mWm}^{-2} \pm 30\%$. The choice of this exposure level was based on a detailed survey of seventeen macro-cellular base station sites in the UK, which found a maximum power density of 8.3 mWm^{-2} [10]. Exposure to members of the public from Microcell and Picocell base stations may exceed 100 mWm^{-2} [11], so this does not represent a maximum exposure for all types of base station. The variation in power density over the region occupied by the seated volunteer (a 1 m by 0.9 m plane orthogonal to the antenna boresight) is no more than $\pm 3.2 \text{ dB}$. The power density in the sham mode is 54 dB lower than for the transmit mode, and is a CW signal.

The GSM signal is representative of a GSM macro-cell base station without downlink power control on the traffic channels. The main characteristics of the GSM signal are given in Table 3. The pulse shape and inter-slot guard interval, Fig. 5(a), conform to the GSM specifications [3]. There are two traffic channels, one at 886.8 MHz and one at 1877 MHz, and two broadcast channels, one at 888.8 MHz and 1879 MHz and these signals are transmitted simultaneously. The broadcast channels have all eight slots in the frame continuously transmitted at a constant power level. The traffic channels have constant pulse amplitude but variable slot occupancy, the slot occupancy being generated stochastically, Fig. 5(b). The peak amplitude of the signal at the four frequencies are approximately equal.

Table 3: Main characteristics of GSM signals from the base station exposure system.

GSM base station	Included in MTHR exposure system
GSM 900 band	Yes
GSM 1800 band	Yes
Traffic channel	Yes
Control channel	Yes
Variations in slot transmit power on traffic channels (downlink power control).	No
PSK modulation	Yes
GSMK mask for pulse shape	Yes
Variable slot occupancy for traffic channel	Yes -this is generated stochastically
EMC emissions from base station	No
Fading multi-path effects	No

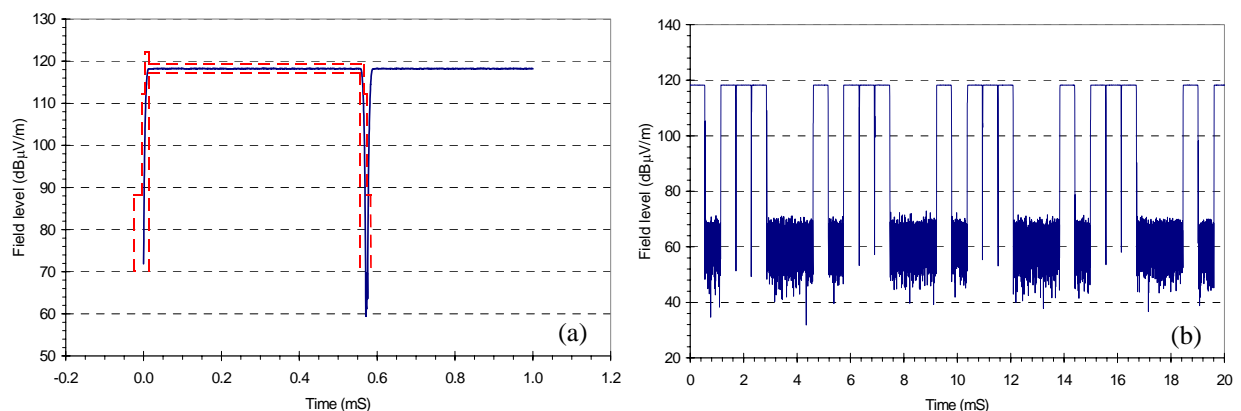

Figure 5. GSM 900 Traffic Channel: (a) Single pulse, dashed-line shows pulse limits from GSM specifications [3], (b) Multiple pulses, showing slot occupancy within the GSM frames.

The UMTS mode is based on test mode 1 specified in the 3GPP standard [12] and is representative of a realistic traffic scenario with high peak to average ratio. It is a single channel with 5 MHz bandwidth, as shown in Fig. 6. The signal was decoded using an Agilent PSA spectrum analyser, and the results are shown in Table 4

Figure 6. Peak amplitude versus frequency for UMTS signal.

Table 4. Composition of UMTS signal

Signal component	Level ¹
Common Pilot Channel (CPICH)	-24.009 dBc
Primary Synchronisation Channel (PSCH)	-43.09 dBc
Secondary Synchronisation Channel (SSCH)	-43.82 dBc
Number of active channels	none
Maximum power for inactive channel	-21.762 dBc
Average power for inactive channel	-27.093 dBc

Note.

1.
$$dBc = 10 \log_{10} \left(\frac{\text{channel power}(W)}{\text{Power at centre carrier frequency}(W)} \right)$$

2. Exposure systems for in vitro studies.

Great care must be taken when designing and calibrating experimental exposure systems, and the scale of this task should not be underestimated when planning a study. As well as establishing known and accurate exposure levels with suitable signal characteristics, all other environmental factors must be considered and relevant parameters monitored during the experiments. A high efficiency at inducing SAR is desirable, since any power losses within the exposure device are likely to cause heating in the samples in addition to the heating due to their dielectric losses. Transverse Electromagnetic (TEM) cells [13], which are widely used for generating exposures, generally have a low efficiency for inducing SAR in small samples. Sample containers should not be placed directly on the conductors of the TEM line, as this allows thermal conduction to occur. For matched systems, heat may be transferred from the termination, and this should be remote from the exposure set up. For exposure systems used in incubators, there should be sufficient airflow to ensure the samples are at the same temperature as the incubator. In this respect open-sided transmission lines are better than closed TEM cells. It is essential to measure the heating of the biological samples that occurs during the exposure, and assess the effect that this will have. Where such heating occurs, rate of temperature rise measurements will over-estimate the SAR arising from absorption of RF energy. Systems with high VSWR may give higher efficiencies, but uncertainty in the position of the standing wave will lead to large uncertainties in the exposure. The position of the standing wave is dependent on the complex impedance of the source and termination. Determining the level at which samples should be exposed for a particular experiment is difficult. Whilst SAR measurements in homogeneous phantoms can be used to determine conservative estimates for the maximum 1 g or 10 g averaged SAR from a device, they cannot predict the SAR level in a particular biological tissue within a person or animal exposed to electromagnetic fields, and this can usually only be determined by computer simulations.

Calibrating *in vitro* exposure systems is difficult, and dosimetry may rely heavily on computer simulations. Systems that operate at 37°C, should be characterised at this temperature, as the conductivity of the samples, and therefore the energy absorption, will change with temperature. For multi-well plates the exposure will not be the same for all the wells. This should be taken into account when designing the experimental protocol. Uniformity of exposure may be enhanced by filling the regions between the wells with dielectric material having similar permittivity to the samples. Non-uniformity of samples and meniscus effects add to exposure uncertainty [14]. Whilst it is possible to measure the SAR in the media containing cells or organisms, the measurement techniques generally have insufficient resolution to determine the SAR within the biological material of interest. There is a clear need to develop techniques of dosimetry with much higher spatial resolution for this purpose (micro-dosimetry).

Two types of system were used to generate exposures for the *in-vitro* studies in the MTHR programme; a TEM cell for use in incubators (University of Nottingham) and open-sided transmission lines for use in microscope systems (Babraham Institute, Cambridge). The systems were calibrated at NPL to provide exposures that were traceable to National Standards. The method of calibration is to use a 1.4 mm diameter electric field probe to compare the electric field within the exposed samples with a known electric field in the same material generated within a matched waveguide system [15]. This may require several litres of sample at 900 MHz for the measurement in the matched waveguide. The measurement in the exposure system must be performed using a higher input power than is used for the experiments, and the results scaled to the correct power level. This is because the small size of the E-field probe yields poor sensitivity. A sample depth of at least 5 mm is necessary to avoid errors. For these systems, the field strength in the air above the sample is much higher than the field in the sample itself, and the probe will over-read if the sensors are not immersed sufficiently in the sample. Accuracy is improved by using the same power sensor to determine the input power to the waveguide and the exposure system. The material density must be measured to determine the SAR level, but the conductivity of the material is not used in the calculation using this method. The temperature rise in the samples was measured using a SPEAG TV1V3 temperature probe for different power levels.

The system used by the University of Nottingham for previous studies into effects of RF exposures on nematodes [16, 17, 18] has a twenty-four well *petri* dish located within the TEM cell. The exposure system is placed inside an incubator. As part of the MTHR programme, the performance of this system was assessed at NPL. Fig. 7(a) shows the measured SAR value at the centre of a 1 ml sample of K-medium (permittivity 78.30 – 22.96 j at 900 MHz and 22.5°C) for each of the wells in the *petri* dish. There is considerable variation in the SAR level between wells in the *petri* dish. The SAR level averaged across all the wells was 0.0141 Wkg⁻¹ for 1 W at input power, so the system has relatively low efficiency at inducing power absorption in the samples. It is important to note that the SAR was measured in the K-media used to support the nematodes, and not within the nematodes. The variation in SAR with sample volume and probe height is shown in Fig. 7(b). Note that the probe is over-reading as it comes into proximity of the surface of the sample because the field in air above the sample is much higher than the field within the sample.

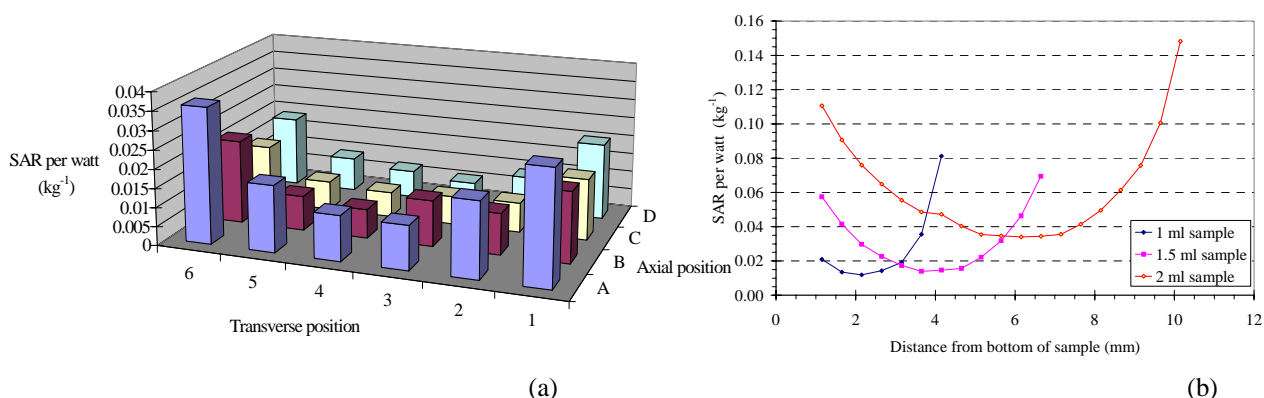

Figure 7. (a) Variation in SAR level for different wells in a multi-well petri-dish, (b) Variation in SAR with probe height for different sample volumes.

The temperature rises at the centre of the samples were measured at NPL in a temperature controlled laboratory. Cycling the power on and off allowed heating due to the RF power to be distinguished from any changes in the ambient temperature. It became apparent that the power loss in the TEM cell was giving rise to additional heating of the samples, and this was not predicted from SAR calculations. To reduce this loss, the following modifications were made to the system; the foam filler that originally filled the lower chamber of the TEM cell was removed; the BNC connectors used at either end of the TEM cell were replaced with APC3.5 connectors (BNC connectors are for frequencies up to 500 MHz); the TEM cell was silver-plated. The results of the sample temperature measurements before and after modification are shown in Fig. 8 and in Table 5. The temperature measurements were repeated with the system in the incubator used for the experiments and the results confirmed. Previously reported effects from the studies could not be replicated once the unwanted sample heating caused by the exposure system was reduced in this way [19]. It is probable that the nematodes used for the studies were sensitive to the temperature changes that were occurring in the original exposure system.

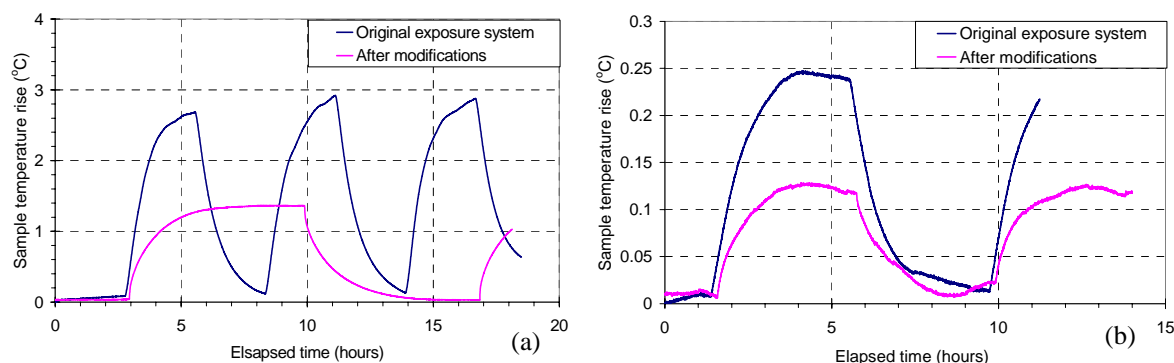

Figure 8. Temperature rises in samples for; (a) an input power of 10 W, (SAR level 0.14 Wkg⁻¹) and (b) an input power of 1 W (SAR level 0.014 Wkg⁻¹) before and after modification of the exposure system.

Table 5: Performance of exposure system before and after modification.

Parameter	Original exposure system	After modification
Power loss at 900 MHz	8.47%	1.09%
Sample Temperature rise for 1 W input power	0.25°C	0.12°C
Sample temperature rise for 10 W input power	3.6°C	1.4°C
Average SAR level in samples for 1 watt input power.	0.014 Wkg ⁻¹	(0.014 Wkg ⁻¹)

The system used by Babraham Institute [20, 21] is shown in Fig. 9. An inner conducting plate, and two outer conducting plates form an open-sided TEM transmission line. The sample is placed on the lower conductor directly above an aperture, and this allows it to be viewed with a microscope during exposure. Table 6 gives the measured SAR levels for 1 watt input power at five positions (Fig. 10) in HEPES and DMEM. The measurements were made at 22.2°C. This is because the National Standard for SAR is controlled at this temperature. However, the exposure system is normally used in an incubator at 37°C. The dielectric properties for these materials at 22.2°C and 37°C are given in Table 7. The SAR levels in the sample will be proportional to the conductivity, so the measured SAR values must be adjusted to account for temperature. The efficiency at inducing SAR in the samples is twenty times that of the Nottingham system, due to the smaller separation of the conductors, and no significant sample heating occurs.

Conclusions

The MTHR programme has adopted sound metrological principles to ensure the studies funded within the programme produce meaningful, and reproducible results. The National Physical Laboratory has provided consultancy to the researchers within the programme and has characterised and calibrated some of the exposure systems used. Human volunteer studies into handset exposure have used standard exposure handsets that generate the main characteristics of both the RF and magnetic fields produced by real GSM and TETRA handsets. The exposure level of 1.4 Wkg⁻¹ 10 g averaged SAR ensures volunteers are not exposed above ICNIRP guideline levels. The base station exposure system produces exposures representative of a GSM macrocell base station at 10 mWm⁻². The system also generates representative UMTS signals. Both systems facilitate double blind experimental protocols. For the *in vitro* studies within the programme, the system used to generate exposures have been traceably calibrated to National Standards at NPL. Unwanted heating effects in one system were rectified, and previously reported effects of RF exposure could not then be replicated.

TOWARDS A STANDARDIZATION OF SAR NUMERICAL EVALUATION

Abstract

The numeric evaluation of the specific absorption rate (SAR) referred to a certain quantity of biological tissue, plays a main role when radioprotection aspects connected to the interaction between humans and electromagnetic (EM) fields are investigated, as highlighted in the related guidelines both in European Community (ICNIRP) and in USA (IEEE C95.1).

Nevertheless, it is important to observe how SAR values are strongly influenced by many factors as, for instance, the shape of the volume containing the reference mass; such a shape is imposed as cubical in IEEE guidelines, whilst this is not clearly stated in ICNIRP ones. Moreover, several other aspects, such as the optimum discretization step or the treatment of internal air (just to mention some of them), cause discrepancies among results obtained by different research groups.

In this work an overview on some SAR algorithms is firstly presented, and a discussion on their potential differences reported. Then, such algorithms and new ones proposed by the authors, are used to evaluate the SAR in some practical human-antenna interaction cases. The remarkable differences highlighted from the comparison, enforce the necessity to individuate an algorithm to be elected as “canonical”, as discussed in conclusion of the work.

Introduction

The frequent exposure to the field emitted by electromagnetic (EM) sources is nowadays a matter of fact; consequently, in recent years, there has been an increasing public concern about the possible risks for human health due to the interactions with antennas. For this reason, the major public organizations in the world have established safety guidelines for radiofrequency (RF) exposure, as for instance the recently revised IEEE RF Safety Standard C.95.1-2006 [1], adopted in United States, and the International Commission on Non-Ionizing Radiation Protection (ICNIRP) Safety Standard [2], adopted in European Community. Such guidelines are based on the specific absorption rate (SAR) averaged over a certain reference tissue mass, usually 1 g, 10 g or the whole body mass; safety limits are accurately fixed distinguishing among different categories of workers and different body parts, and they are also frequently updated as a consequence of the results produced by the scientific community. The last confirmation of that is given by the introduction for the first time in a guideline [1] of new safety limits specific for the pinna, after the publication of some works, aiming at demonstrating the necessity of paying due attention to the anatomic details of the ear and to their effects in the exposure to cellular phones [3]-[5]; such diversification had not been considered neither in the previous IEEE standards [6], [7] nor in ICNIRP ones.

Nevertheless, in contraposition to the constant attention dedicated to the refinement of the safety limits, diversifying them in terms of kinds of workers, exposure time and exposed body portions, it is quite evident a lack of indications about how the SAR should be evaluated; indeed, despite the apparent easiness of the formulae for the SAR evaluation, such relations actually open themselves to different interpretations which could cause discrepancies in the estimation of the absorbed energy. As well known, in fact, the SAR is defined as the “time derivation of the incremental energy absorbed by, or dissipated in, an incremental mass contained in a volume element of a given density, normalized to that mass”, which can be synthesized as:

$$SAR = \frac{\partial}{\partial t} \left(\frac{\partial W}{\partial m} \right). \quad (1)$$

In the context of RF and/or microwave (MW) exposure, where the energy absorption by tissues is only due to the Joule effect, two more convenient forms are often used, allowing the SAR evaluation from either electric field or temperature measurement through the following formulae:

$$SAR = \frac{\sigma |E|^2}{2\rho} = c \frac{\Delta T}{\Delta t}, \quad (2)$$

Where σ [S/m] is the tissue conductivity, E [V/m] the electric field, ρ [kg/m³] the tissue density, c the tissue specific heat capacity and ΔT [°C] the temperature change caused by the exposure for a time Δt [s].

Consequently, considering the first of the (2), the SAR averaged over a certain reference mass, can be written as:

$$SAR_{rm} = \frac{\int_{V(rm)} \sigma |E|^2 / 2 \, dv}{\int_{V(rm)} \rho \, dv}, \quad (3)$$

Where rm is the reference mass (usually 1g, 10g or the whole body mass) and $V(rm)$ is the volume containing rm .

It can be noted that, although the shape of the volume containing the reference mass does not affect the divisor in (3), which is anyhow equal to rm , its impact on the dividend could be relevant; the distribution of the electric field, in fact, varies greatly from point to point inside the tissues, so that the use of different volumes could generate strong discrepancies.

It is reasonable wondering, hence, how the shape of the volume containing the reference mass can impact the SAR value itself and if, consequently, such a shape must conveniently be standardized. Can, for instance, the SAR averaged over 10 g of tissue assume a different value if the volume shape is changed? If so, which is the most appropriate shape to be considered?

The just opened problem is almost completely neglected in international guidelines. Despite the common sense would suggest that a spherical volume should be the most logical choice, because it does naturally select the set of points which are as close as possible to the evaluation point, IEEE guideline bases its safety limits on cubical volumes. Even more debatable is the position assumed on ICNIRP standards, where the absolute lack of indications in matter, leave the scientist the faculty of the choice.

Moreover, it is commonly accepted from the scientific community, that the use of numerical dosimetry for the energy absorption estimation is the most appropriate approach; experimental dosimetry, in fact, evidences strong difficulties both in using real subjects and in carrying out adequately accurate phantoms, capable therefore to correctly reproduce the human characteristics. Vice versa, the use of EM full-wave methods, such as the Finite Difference Time Domain (FDTD) algorithm or the Finite Element Method (FEM), jointly with the availability in literature of some accurate numerical phantoms, as for instance the one proposed in [8] or the one proposed in [9], allows the rigorous evaluation of the SAR also in complex realistic human-antenna exposure problems. However, when numerical methods are used, a spatial discretization must be implemented, thus accentuating even more the problems connected to the SAR evaluation. In such a case, in fact, the averaged SAR can be computed through the following formula:

$$SAR_{rm} = \frac{\sum_{i \in \bar{V}(rm)} \sigma_i |E_i|^2 / 2}{\sum_{i \in \bar{V}(rm)} \rho_i}, \quad (4)$$

where the index i indicates the generic elementary cell of the discretized space and $\bar{V}(rm)$ the discretized volume containing the reference mass rm . The use of a volume $\bar{V}(rm)$ consisting of several cells, is itself a degree of freedom and consequently a source of non-uniqueness of the results, the SAR value being dependent on which cells are chosen, among the several possible, to better represent the desired volume shape. Moreover, also the spatial discretization step could play a major role: a space step as large as a significant portion of the reference mass, for instance, besides emphasizing the just mentioned problem, causes strong discrepancies between rm and the actual considered averaging mass.

To the topics now pointed out, some others can be added, each one increasing the uncertainty to the estimated SAR values. The peak SAR values, for instance, are often founded in points close to the human surface, where

the chosen volume shape must be modified in order to consider only tissue and not air. Which is the best algorithm in that sense?

Moreover, as well known, if the FDTD method is used, the obtained electric field components are not centered in the elementary cells [10]. Recently, some algorithms have been proposed to refine SAR calculation [11], and they are herein discussed.

Furthermore, another key-point is the one of how to treat the presence of internal air, which is also here specifically addressed.

More specifically, in the following sections some commonly used SAR algorithms will be described and compared, and some new ones proposed by the authors presented. Such algorithms are then applied to a difficult case of interaction between humans and radio base station antennas (RBA) using both cubical and spherical reference volumes, and results showed and discussed.

Common SAR numerical algorithms

In this section, a brief overview of the most commonly adopted algorithms for the numerical evaluation of the SAR, is presented. Despite the appreciable differences among the algorithm structures, it is important to highlight here that the main goal of this treatment is neither the individuation of an algorithm to be elected as a reference, nor the eventual discredit of some of them; on the contrary, in fact, what is sustained in this work is that, although different numerical strategies give out different SAR values, none of them contravene any of the indications reported in the safety guidelines.

One of the usually adopted approaches, for instance, computes the SAR_{rm} on a certain point by considering the contributes coming from the cells which belong to a cubical volume centered in that point. In [12] and [13] such a volume is prefixed, i.e. is the same for each computation point, and it is dimensioned in order to roughly contain the reference mass. The non modifiability of the volume shape causes the evaluation of the SAR in presence of air together with tissues and consequently an averaged value obtained integrating over a mass different from rm . In order to avoid the evaluation of the SAR in cases where a too large portion of the volume does not contain tissues, a maximum tolerable percentage of air is imposed: if the percentage of air is superior to the fixed limit, SAR remains undetermined.

It is important to observe that such an approach does not allow the evaluation of the absorbed energy in the most external points of the exposed target where, though, high SAR values or even the peak SAR itself, are located.

Furthermore, also where the volume does not contain air, it is often impossible to reach exactly rm using a cube, the number of needed cells being strongly dependent on the discretization step.

In order to avoid some of the listed problems, parallelepipeds instead of cubes are used in [14], but also this solution is not devoid of lacks; such a choice, in fact, forces the use of a volume which is unbalanced respect to the evaluation point and, consequently, causes the use of too far contributes.

A first improvement of the previous techniques can be obtained through the use of a cubic volume which dynamically adjusts itself in order to consider exactly the rm and tolerates up to a certain percentage of air, as proposed in [11]. The algorithm builds a sequence of cubes of dimension progressively increasing till a mass superior to rm is reached. At each step the percentage of air is evaluated and if it is greater than the prefixed limit, the SAR in that point remains undetermined. Vice versa, the last cube of the sequence with mass inferior than rm is used as the core for the SAR evaluation and only an accurately evaluated portion of the adjacent cells is added in order to exactly reach rm . Anyhow, a big limit of this algorithm remains: the incapability to determine the SAR in points closed to the surface of the exposed target; in [15] a further improvement in that sense is proposed. The concept of a volume perfectly cubical is not considered indispensable anymore; the cells are assembled around the reference one by following established criteria and excluding the air. The algorithm, here named Adaptive Cube (AC), stops the insertion of new cells when the total mass is equal to rm for each computed value, but the shape of the volume is given by the set of cells which better approximate a cube intersected with non-tissue points. In such a way, in each point, included those belonging to the most external regions, the SAR can be evaluated.

The comparison among the presented numerical techniques shows that even radically different algorithms for the evaluation of the SAR can comply with the few indications reported in RF safety guidelines, despite it is easily

predictable that they could generate discrepant results. Consequently, an integration of the guidelines with detailed indications on a SAR numerical algorithm to be elected as a reference, appears to be at least expected.

New kinds of SAR algorithms

The conceptual differences among the commonly used algorithms for the SAR numerical evaluation and the consequent observations reported at the end of the previous section, pave the way to a more deep theoretical discussion about how the algorithms should be conceived. Even if at a first glance it could seem a mere implementation problem, it addresses instead to a more general consideration: which is the most suitable volume shape for the SAR evaluation? If it is true that when numerical methods and orthogonal meshes are used, it is quite easy and natural to choose cubical volumes which contain 1g or 10g (the rm) of tissue, it is as much true that the acceptance of such an assumption signifies to be aware of the limits which derive from that, and that the obtained results could be at least debatable.

Anyhow, even if, for instance, the AC algorithm is basically oriented towards cubical shapes, the eventual presence of air could cause a strong deformation of the volume, such as in the case of the SAR evaluated in the fingers, where the cube becomes more likely similar to a thin parallelepiped. This is not surprising, the choice of the cube being justified only by its implementation easiness; nevertheless, it is reasonable wondering which should be the most appropriate volume, regardless to eventual implementation problems.

To the opinion of the authors, there is no doubt that a spherical volume is the best one. Spheres, in fact, select the most close cells to a reference point, thus allowing the most natural evaluation of the SAR; any other volume, in fact, would take into account too far contributes, as for the cube case, where the vertexes are considered instead of more close points.

Nevertheless, to adequately take into account a spherical volume when discretized spaces are considered, some observations are necessary. In a continuous space, in fact, it is possible to determine an ideal sphere (ideal circle in 2D) which contain exactly a quantity of tissue equal to rm , but in a discretized space this is quite

Figure 1. Representation of the ideal circle which includes the rm .

complicated. For the 2D case, an hypothetical ideal circle is reported in Figure 1; the yellow cell in the center is the one where the SAR must be evaluated. Some of the cells are entirely contained in the ideal circle, whilst some others (the violet ones in Figure 1) are intersected by that circle; such cells are called here “peripheral cells” and will play a major role in the formulation of new algorithms. The SAR, in fact, should ideally be calculated by adding the contribute of the internal cells to the contribute of the partial volumes of the peripheral cells, so that the approximation of such partial volumes becomes the real difficulty of spherical algorithms.

In the following four new algorithms will be presented, all based on spherical volumes, even though the same strategies can be easily applied to cubical volumes.

A: Onion Skin Algorithm

The first algorithm which is here proposed considers a sphere as the reference volume and, when necessary, modifies the shape in order to include only tissues and not air. The strategy that regulates the addition of a new cell to the partial volume, gives the name to the proposed algorithm: “Onion Skin” (OS); if the mass contained in a sphere of radius r (onion) is inferior to rm , in fact, new cells are added selecting them out among those belonging to the layer which radius is $r+1$ (skin). Such an algorithm is similar to the AP one proposed in [15] apart from the shape of the volume.

The main steps of the algorithm for the evaluation of the SAR_{rm} in a cell of coordinates $\langle x, y, z \rangle$ can be synthesized as follows:

Figure 2. Onion Skin algorithm applications examples.

1. initialize the radius $r = 1$ and set the center in $\langle x, y, z \rangle$;
2. select the set of possible candidate cells as those belonging to the layer of radius r centered in $\langle x, y, z \rangle$ and representative of tissues (air is excluded);
3. add one of the individuated cell to the partial volume and compute the new partial mass pm .
4. repeat step 3 until all the cells individuated in 2 have been added or the condition $pm \geq rm$ is verified;
5. if $pm \geq rm$ has not been verified yet, impose $r = r + 1$ and come back to 2. Else (the volume is founded) go to 6;
6. Evaluate the SAR_{rm} by using the individuated volume.

The method guarantees that the desired 1g or 10g of rm are obtained with a tolerance on the order of a fraction of the last added cell mass. It is quite evident that the algorithm is based on the iterated addition of layers to the central cell until rm is reached; it is highly probable, though, that the last layer will not be completed, thus causing an unbalancing of the volume respect to the cell in $\langle x, y, z \rangle$. In Figure 2, a bi-dimensional schematization of the volume individuated by the OS algorithm is reported for a simple case of absence of air and supposing that 25 cells guarantee a mass of almost rm . The different colors of the cells individuate different layers. More specifically, in Figure 2a the reference cell (the yellow one) is supposed to be far enough from every air region so that for each successive layer all the cells can be considered potential candidates to be part of the averaging volume; as apparent, three complete layers and a partial one are needed. The cells of the last layer, however, could be chosen in different ways as evidenced in Figure 2b, and consequently the obtained SAR could assume different values. This represents the most substantial lake of the OS algorithm. Finally, Figure 2c shows what happens when the evaluation cell is quite close to air regions, with the consequent modification of the volume shape in order to guarantee anyhow an averaging mass equal to rm as well as the use of only tissue cells.

B: Graded Peripheral Cells Algorithm

As previously observed, the best way for considering spherical volumes in orthogonal meshes, would be that of taking into account the whole contribute coming from all the cells entirely contained in the ideal sphere, and the partial contribute given by the peripheral cells. The problem, actually not trivial, consists on the accurate evaluation of the partial volume to be considered for each of the peripheral cells; this problem is quite difficult to solve analytically because of the high number of possible intersections between spheres and cubes: approximations are, hence, strongly necessary.

The herein proposed approach, called Graded Peripheral Cells (GPC), considers an equal fraction of all the peripheral cells, regardless to the effective volume individuated by the ideal sphere (or ideal circle in 2D). The algorithm analyzes all the non-air cells around the evaluation point, and marks them as internal, external or peripheral, respect to the ideal sphere; in order to perform such an operation, the number of vertexes internal to the sphere is computed.

Once such a preprocessing analysis has been performed, the mass of the internal cells is known, as well as the remaining quantity necessary for reaching rm . Such a quantity is considered as equally distributed among all the peripheral cells which proportionally contribute to the final SAR value.

In Figure 3 the individuated resultant volume is reported for the same case of Figure 2a. The small internal squares sketched inside the peripheral cells, represent the considered portion of mass. By comparing such a volume with the one obtained with the OS algorithm, it can be noticed how the problem of the unbalancing respect to the central cell is substantially bypassed. Nevertheless, the assumption that all the peripheral cells contribute with the same mass, seems to be too approximate, because some of the cells are only slightly intersected from the ideal sphere whilst some others are almost completely internal. The next proposed algorithms can be considered as a refinement of the GPC one, aimed at better approximate the ideal situation described in Figure 1.

C: Graded Peripheral Vertex Algorithm

The Graded Peripheral Vertex (GPV) algorithm represents a more refined version of the GPC algorithm. As previously shown, in fact, in GPC the same portion of mass is considered for each one of the peripheral cells; if a method is found for discriminate how much of a cell is internal to the ideal sphere, a non-uniform weighting can be effectively applied. Actually, the same strategy used for discriminating if a cell is or not peripheral, can be extended in that direction; a cell is peripheral, in fact, if at least one vertex is internal to the ideal sphere and contemporaneously at least one vertex is external. The number of internal vertexes, hence, could be a good parameter to be used. Despite it is still an approximation, it is evident that a cell with only one internal vertex contributes with a portion of its volume larger than that of a cell with more internal vertexes.

The GPV algorithm, hence, calculates the portion of a peripheral cell to be considered, proportionally to the number of internal vertexes; more specifically, if $1 \leq n \leq 8$ ($1 \leq n \leq 4$ in 2D cases) is the number of internal vertexes of one of the examined cells, then $n/8$ of its mass is considered. Figure 4 shows, reporting also the number of internal vertexes for each peripheral cell, how the application of the GPV algorithm allows a better distribution of the mass respect to the GPC and the OS ones, increasing the accuracy of the approximation respect to the ideal case of Figure 1 and thus improving the quality of the result.

D: Graded Peripheral Vertex-3 Algorithm

The Graded Peripheral Vertex-3 (GPV3) algorithm is a modification of the GPV algorithm, where the contribute of each peripheral cell is not proportional to the number of internal vertexes n , but to its cube (its square in 2D), i.e. to n^3 . This criterion is based on the observation that the dependence of the internal volume on the number of internal vertexes is, in most cases but not always, almost cubical. In such an algorithm, hence, the mass of a cell is divided into 64 parts (16 in 2D) and $n^3/64$ is the fraction of mass (and volume) considered for a peripheral cell with n internal vertexes.

Even if none among GPV and GPV3 is definitively better than the other, above all in 3D cases the GPV3 seems to guarantee better approximations.

Results

In this section some of the presented algorithms are tested on a practical case and results compared and discussed. More specifically the difficult problem of the interaction of a human with the field emitted by a radiobase station

Figure 5. E-Field levels in the studied case

Peak SAR comparison		
SAR Algorithm	Peak SAR (1g)	Peak SAR (10g)
Adaptive Cube (AC)	27.93	14.39
Onion Skin (OS)	27.00	14.32
Graded Peripheral Cell (GPC)	27.65	14.73
Graded Peripheral Vertex (GPV)	27.89	14.78
Graded Peripheral Vertex-3 (GPV3)	28.03	14.85

Table I. Peak SAR values using different algorithms.

antenna has been solved by using the FDTD method [16], and the SAR averaged over 1g and over 10g of tissue has been evaluated in each point of the exposed subject (which is the numerical phantom proposed in [8]). In Figure 5 the electric field distribution in a section of the head is reported. Five different algorithms have been used: the AC one, representative of the cubical shape algorithms, the Onion Skin one, which applies the same strategies of the AC but to spherical volumes, and the three successive refinements, respectively GPC, GPV and GPV3. The other presented algorithms, instead, have not been tested, because their inability to evaluate the SAR in superficial points makes the comparison with most sophisticated strategies impossible.

In Table I the peak SAR values are reported both for $rm = 1g$ and for $rm = 10g$. It can be observed that all the tested algorithms give comparable results. This is not surprisingly: even if the algorithms are quite different, in fact, the peak SAR is found in the proximity of the phantom surface where the electric field assumes the highest values all around a region as large as many rm . In such points, the volumes are also strongly deformed by the phantom shape, so that the refinement strategies becomes unappreciable. Anyhow, it is important to recall again that, among the possible, only algorithms which can evaluate the SAR everywhere in the phantom have been tested; the others algorithms, such as the one proposed in [12] and [13] or the one proposed in [14], would have been unable to determine the SAR in such points. This observation is itself enough to justify the requirement of a standardization of the SAR numerical evaluation techniques.

Figure 6. AC versus OS: percentage difference in each phantom point.

In order to appreciate, though, the differences among the various algorithms, all the SAR values, and not only the peak one, should be compared.

In Figure 6, for instance, the percentage difference among AC and OS is graphically reported. The chromatic scale, from blue to red, represents increasing differences from 0 up to 45%. It is quite apparent the strong diversity in some investigated phantom points, even though only the shape, and not the strategy, differentiates the algorithms.

In Table II, instead, the GPV3 algorithm is used as the reference one, and the percentage difference with the others is reported. More specifically two parameters are computed: the average percentage difference and the maximum percentage difference.

Percentage Difference				
SAR Algorithm	SAR (1g)		SAR (10g)	
	Average %	Maximum %	Average %	Maximum %
AC versus GPV3	8.43	99.08	5.12	69.95
OS versus GPV3	6.90	95.39	3.31	53.71
GPC versus GPV3	4.93	90.14	0.14	3.04
Graded Peripheral Vertex (GPV)	2.66	42.89	0.08	2.33
Graded Peripheral Vertex-3 (GPV3)	---	---	---	---

Table II. Average and Maximum percentage difference respect to GPV3 algorithm.

Through the analysis of the data reported in the table, some conclusions can be drawn. First of all, by improving the accuracy of the algorithms, all the percentages decrease. As expected, hence, by using more refined spherical algorithms a better discrimination of the absorbed power in the various points can be performed, so that the SAR values can be better estimated. Also, it can be observed that differences referred to the SAR_{10g} are always inferior to those referred to the SAR_{1g} and this for two different reasons: first of all, by increasing the rm , the consequent smoothing effect due to the integration over a bigger volume causes the attenuation of the differences among the methods. Secondly, the number of peripheral cells increases with the volume and the contribute of each of them becomes less relevant.

Even more interesting are the deductions coming from the analysis of the maximum percentage error; two sophisticated algorithms, such as OS and GPV3, give in some points difference up to 90% for the SAR_{1g} and up to 50% for the SAR_{10g} . Even two quite similar algorithms, GPV and GPV3, show strong differences in the 1g case. In order to better appreciate the impressive differences among the algorithms in every points of the phantom head, finally, the percentage difference of GPV3 respect to OS and respect to GPC for the SAR_{1g} are reported in Figure 7.

Conclusions

In this work some commonly adopted algorithms for the numerical evaluation of the Specific Absorption Rate (SAR) averaged over a certain mass have been reported and some new ones have been presented and compared. Among the most important conclusions which can be drawn, the main aspect seems to be that of the necessity of a standardization of the techniques for the SAR calculation. The discrepancies among results obtained through different algorithms are impressive, even though all of the tested techniques do not contravene any of the indications, probably inadequate, reported in the most important radiofrequency safety standards. This enforces, also, a more detailed discussion about the consideration of local SAR values.

The work itself gives some indications in that sense, discussing the role plaid by the shape of the integration volume along with other important issues. The use of a spherical volume rather than a cubical one, represents for the authors the main necessary modification, and the four proposed algorithms could be used as the starting point which paves the way to a more deep discussion.

Abstract

Whole-body averaged and local SAR depends on many factors including stature, gender and posture of the exposed subject. In RF dosimetry, various numerical phantoms of women and men are gradually becoming available as well as numerical techniques able to virtually rotate the main joints in order to change their posture. Other variables which deserve investigation are field polarization and impinging direction of the incident wave. To assess the SAR distributions in these structures a high spatial resolution of the human numerical models is mandatory. At the same time, it is usually requested to model a large embedding domain which may accommodate a near field source. This imposes the use of subgridding techniques. Practical examples of the FDTD implementation with a domain refinement algorithm, in the range 100 MHz – 4 GHz, are reported

Introduction

Numerical phantoms involving sophisticated complex permittivity representations of the human body are a useful tool for investigating the connection between external fields and induced internal SAR. These phantoms are obtained either by image segmentation and assignment of the proper permittivity values to each tissue or by semi-automatic methods which take into account the complex permittivity variations into every tissue. Both methods use sets of anatomical images obtained by CT (Computerized Tomography) or by Magnetic Resonance Imaging (MRI).

The human exposure was first studied by using models of a man in standing position frontally impinged by a plane wave with vertical polarization, having these states been recognized as generally maximizing the absorption. Nevertheless, these conditions (male model, standing position and plane wave) are too generic to accurately evaluate the exposure in a realistic environment. Different postures, body shape and composition can determine SAR differences. A number of postures have already been studied [1][2] and, in the last years some works focussed on the gender differences [3].

After having developed their own male [4] and female phantoms [5], the authors used them in some works dedicated to the understanding of the differences found in the whole body averaged SAR between male and female [3][6].

Recently they developed a technique for numerically rotating the main joints of the body preserving, at the same time, a reasonably realistic anatomic aspect. Since a posture in which a subject spends a considerable part of its living time is sitting, arms and legs of the male phantom were rotated in a way to simulate that condition.

A paper published very recently [2] demonstrates that different parts of the body (trunk, limbs or forelimbs) may show their own resonance when stimulated with the proper frequency and polarization. It causes a large variety of conditions determined by the posture and by the parameters of illumination, depending on the relative orientation of the field with specific portions of the body which – in case of a more complex posture than standing with aligned arms – cannot be anymore considered as a simple linear antenna.

The attention is focused on the range of the RF spectrum located above the body resonance (here meant standing, i.e. about 40 or 80 MHz depending on grounded or isolated condition), in which the largest part of artificial sources for broadcasting and mobile communication is allocated: 0.1–4 GHz.

For calculating SAR distribution the Finite-difference time-domain (FDTD) solution method of Maxwell's equations, a widely used numerical technique in computational electromagnetics, has been used. It is commonly retained that only analyses at frequencies corresponding to wavelengths no shorter than 10 times the space sampling size are fairly accurate. But when, at a given frequency, the structures' electrical density augments, such as in biological tissues, wavelengths are unavoidably shortened. Many efforts have then been made to develop local mesh refinement algorithms for the FDTD method. A reported problem of the various attempts is their tendency to become unstable.

In this work, a robust and economic subgridding algorithm has been used [7] to achieve higher spatial resolution in the region of interest. This method, called filtering-based (FB) subgridding, is applied to allow a refined calculation of SAR, while maintaining a rather large cushion of free space all around the bodies.

It is as economic as possible, both in terms of memory request and in the number of floating point operations. To this end we devised a coupling scheme between two FDTD meshes, one of them having an higher resolution by a factor of 3, 5 or 7 than the other. The subgridding algorithm at the fine-coarse interface is based on a spatial-differentiation low-pass filter which is analytically justified. It requires only a certain number of extra floating point operations, but no extra memory allocation.

Firstly this work considers the DAM phantom developed in our laboratories and the numerical algorithm used to rotate the principal joints (arms, legs and hips). A brief description of the used subgridding technique will follow. Finally, some examples about the use of the subgridding technique applied to a real dosimetric problem are shown. In particular it will be studied the comparison of whole body averaged SAR in seated and standing male models undergone to various exposure conditions in terms of H or V polarization and frontal or lateral incidence.

Numerical human body model

A semi-automatic procedure to develop numerical human Dielectric Anatomical Models (DAM) was developed in the last years at the ITC-irst laboratory. The procedure is based on MRI image acquisition and by relating grey levels of each voxel to the proper complex permittivity value. The rationale is briefly described as follow. Detailed description of the technique is reported in [4], [5].

Whole body MRI scanning of a male (height: 1.73 m, weight: 63.8 kg) and female (height: 1.62 m, weight: 48.7 kg) volunteers (to obtain mDAM and fDAM respectively) were carried out. The acquisition of the images was performed by a 1 Tesla whole-body imager (1T, 42.5 MHz); body and head coils were used. Data sets were processed to improve the erected posture of the body. Ankle angle was also modified to ameliorate the contact of the feet with the ground. Afterwards, the images were interpolated, obtaining models of 5,999,472 voxels (fDAM) and of 7,795,509 voxels (mDAM), $2 \times 2 \times 2$ mm³ each. After the processing needed to correct the MR image non-uniformities, an automatic technique has been applied to obtain the dielectric models (Figure 1).

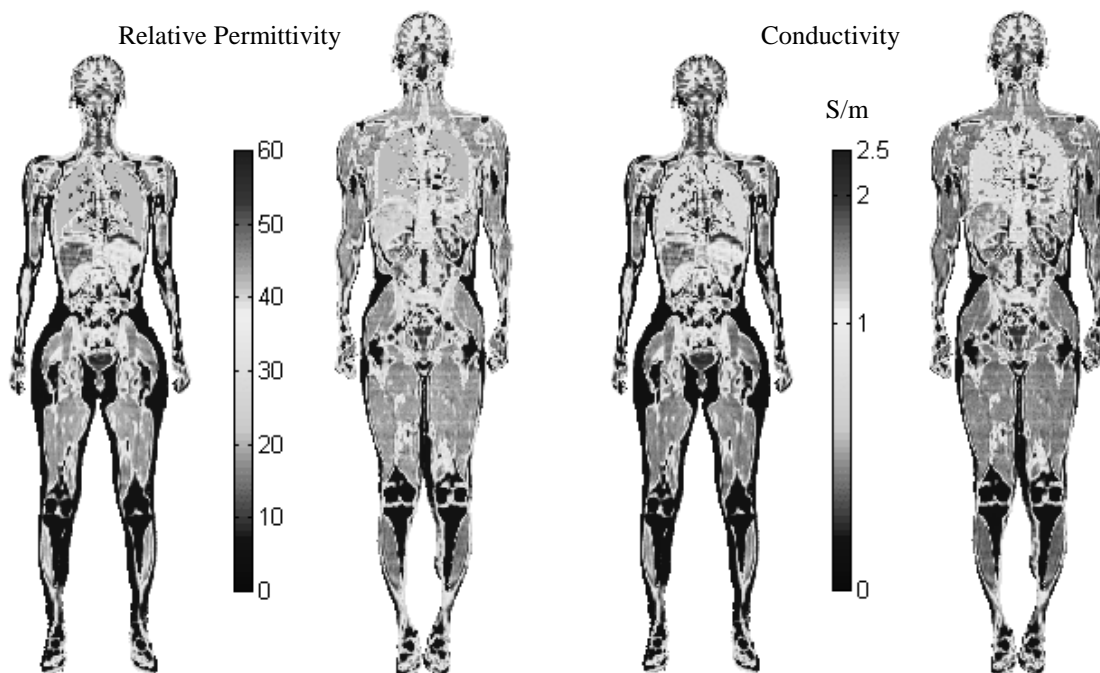

Figure 1. Relative permittivity and conductivity at 2 GHz for the female (left) and the male (right) models

To correlate the image grey levels to the complex permittivity values, transfer functions based on mixture theory were implemented for both high water content and low water content tissues. Since the equations of mixture theory were obtained from data over the frequency range $0.1 \div 18$ GHz, the validity of the transfer functions lies in this same range.

Rotation of joints

In recent dosimetric studies, the attention has been increasingly devoted to the realistic representation of the human body; this means that, while initially only an average male man in standing position was considered, nowadays many phantoms of different heights, weights, genders, ages and positioned in different postures have been represented [1][2]. Among these aspects, the present work focuses its attention to the development of a modified phantom repostured in order to represent a seated man, being this latter a very frequent condition, both for workers and general public. However, aim of this study was not only to reach such kind of result, but more generally to develop a numerical algorithm able to manipulate the original numerical phantom, in order to model as many postures as possible.

The problem of the realistic geometric modelling of humans has been faced in many fields, from dosimetry to mechanobiology or computer graphics [8][9]. In these latter fields a very high level of anatomical modelling have been reached, with accurate representations of the organs both from a geometrical, anatomical and even dynamic point of view. The starting point in these cases is the detailed knowledge of the internal structures, which are segmented [10]. In this way each single structure is not only geometrically well-confined, but also dynamically characterised, and therefore able to discriminate that, for example, only the muscle is able to undergo active contraction or that the rigidity of the bone actually prevent its deformation.

Conversely, the original phantom used in this study is not segmented. While this condition enables on the one side the highest accuracy in the dielectric properties dispersion modelling, on the other side it partially hinders the accuracy in performing joint movements.

Nevertheless, some general criteria are anyway applicable, such as: to deform as little as possible the rigid structures like the bones, to preserve the total length of each deformed part (alongside its central axis), and finally to properly modify some regions (muscle) in order to maintain the total mass amount constant guaranteeing at the same time a good anatomical resemblance. It is evident that, in this case, the criteria are no longer applicable to well-defined districts, but rather to regions principally containing one tissue or the other.

The procedure followed to obtain the seated phantom is summarisable as follows:

- first of all the sub-volumes to rotate were identified and isolated, one at a time, from the remaining part of the body. In this specific case four sub-volumes were obtained: one for the legs, one for the pelvis and the two latter for the arms;
- for each sub-volume some ‘fiducial point’ couples (one point in the subvolume, the other one in the remaining part) were located. These were chosen in correspondence of the interface—the region that will be deformed the least—in order to facilitate the successive re-assembly of the two parts;
- the rotation plane and axis were defined with respect to the sub-volume and this latter was considered as a succession of slices parallel to the rotation plane and one voxel thick;
- each slice was further subdivided longitudinally in order to obtain several geometrical structures (called *fibres* hereafter in the text), parallel one to the other and roughly following the direction of the part to bend. The aim of this operation is to guarantee the necessary continuity alongside the structure (for example the wrapping around the elbows, knees, etc.);
- in correspondence of each slice there was one only *fibre* which passed through the rotation axis. This *fibre* underwent the only rotation operation, whilst, as the *fibres* were away from the central one, they underwent also a deformation. It is worth noting that, considering the slices where the bone was present, the central *fibre* coincided just with the bone and was therefore suitable to represent its rigid behaviour.
- Besides the rotation, other two types of deformations were applied: i) in correspondence of the rotation axis surroundings, in order to guarantee the necessary continuity of the tissue in this region, and ii) the height augmentation of the most external *fibres* containing tissues, applied in correspondence of the middle part of the segment(s) upper (and lower) with respect to the rotation axis. All these operations were applied at *fibre* level.

The first operation consisted in the assignment of a new value—obtained by interpolation of the nearest voxel values—to both the new empty voxels and those superimposed as a consequence of the rotation. The second deformation had instead the aim to reproduce the muscle augmentation as a consequence of its contraction (active in the case of the upper-limb, and passive for the lower-limb). This latter kind of deformation was customizable, by initially setting two parameters which had effect, the first, on the amplitude of the deformation, and the second on the extent of the region to deform. These operations were performed in an automated way through an algorithm implemented by the authors.

The figure 2 shows, as an example, the different effects obtained by applying some kinds of deformations to the DAM's original left arm (a), and thus obtaining a simply rotated arm (b) or a rotated arm with augmented muscle in correspondence of the upper-limb (active contraction, (c)), or both the upper- and lower-limb (active and passive contraction, (d)).

A direct consequence of these kinds of deformations was a little mass variation. In particular, even the rotation without muscle augmentation led to a mass increasing as long as the structure to bend was rather thin (arm, legs), but the mass was found to be reduced while bending larger structures such as the pelvis. Therefore, particular attention had to be paid in assigning the suitable deformation parameters, in order to guarantee the total mass conservation.

A picture of the final result, that is the seated DAM phantom, is shown in Figure 3, laterally on the right.

Figure 2: The pictures show four slices corresponding to the same depth of the DAM arm: in the original position (a), bended with a rotation of 45 degrees (b), as well as deformed to reproduce the muscle contraction, only in correspondence of the upper-arm (c), or both in the upper- and fore-arm. The white curves roughly indicate the regions where the deformations were applied.

FDTD calculation

Following a well known procedure, in classic FDTD [11] one writes centred finite difference analogues of the six partial differential scalar equations corresponding to the two Maxwell's curl time domain ones. Due to the particular choice of the lattice fields' sampling points, such finite equations are second-order accurate, both in space and time. As an initial value problem (IVP) fully explicitly formulated, the classic FDTD method is subjected to a stability condition, the so-called Courant–Friedrichs–Lewy (CFL) condition.

Moreover, the FDTD method needs to be supplemented by a suitable boundary condition (BC) on the outer surface of the computational domain to truncate the lattice and thus overcoming finite memory allocation capabilities. To this end many authors developed special BCs which are known, in the FDTD community, as absorbing boundary conditions (ABCs) or radiation boundary conditions (RBCs). They permit a mesh truncation with a minimum amount of back-reflection into the computational domain.

In our work we implement the anisotropic PML condition [12], which makes use of a uniaxial anisotropic lossy Maxwellian (i.e., unsplit) material. Our absorbing layer depth is standardized to 20 extra cells. Special care has to be given to the 8 corner, the 12 edges and the 6 faces of such an additional outer absorbing lattice. The coefficients for the various sub-regions and other relevant parameters are pre-calculated before the FDTD iterations start. Cubic smooth onsets of the conductivities are also used. A very low residual reflectivity is accomplished.

We also adopt the so-called “pulsed” FDTD method, which makes use of compact excitation pulses and an in-line discrete Fourier transform (DFT) of the system response. The DFT is updated every space sampling point at each time iteration. A plane wave excitation is launched on the six faces of a so-called Huygens' box, by means

of the addition of electric and magnetic surface equivalent currents, which permit the total field, here meant incident+scattered, is present within the box but only the scattered one travels outside his volume. This allows an optimal functioning of the RBCs since they work on fields having lower amplitude than that of the total field and with incidence near to the normal to the boundary. The conditions on this box are parameterized in order to launch the desired excitation (i.e., progressive or regressive plane waves with different polarizations) without changing and/or recompiling the code. The model of the body target is contained in a sub-domain separately dealt with by the subgridding FDTD routine, which works coupled with the exterior one.

In [7] it is demonstrated that refining techniques are prone to instabilities because the interface between fine and coarse grids can trigger the onset and/or the amplification of high frequency components. This is due to the different numerical dispersion properties of the two grids. In particular, components which may freely propagate in one grid may have frequency greater than the Nyquist limit of the other one. Usually these frequencies are over the maximum frequency of interest and then may be treated as spurious components. The countermeasure proposed in [7], and here implemented, is to filter out such frequencies directly at the fine-coarse interface. That is why we call the technique FB-algorithm (Filtering Based).

It is not straightforward to deal with filters in time domain calculations such the FDTD method. In principle, simple low pass filters are applicable by using recursive techniques. The problem is that they would introduce phase delays which generate unphysical propagation and ultimately lead to instabilities. On the other hand, implementing a zero-delay filter would imply having at hand the whole time history of the quantity to be filtered, a thing which is impossible because of the evolutive nature of the FDTD method itself.

The problem has been solved [7] by transforming the temporal double derivative and his higher orders (used to implement the filter) into a set of spatial ones by means of the wave equation. Without entering in details here, the filtering action is obtained by a sort of spatial averaging with given weight coefficients. Acting at the space level permits the in-line updating during the time iterations. This allows a drastic mitigation of the instabilities, giving us the chance of using straight refinement factors of up to 7 or more, without resorting to the recursive nesting of grids (as instead it was usually done in case of use of such high refinements) which is severely computationally onerous.

Results and conclusions

In order to complement the findings of [2] who found that posture may give rise to secondary resonance peaks, a number of frequencies in the range 0.1–4 GHz have been evaluated. For each of them, the male phantom was accommodated in two postures (sitting and standing) and exposed in H or V polarization with the wave impinging the body frontally and laterally. The results are summarized in Figures 3 and 4. Since our method for obtaining the phantom does not allow going down below 100 MHz, we could not evaluate the resonant region of the spectrum. Nevertheless, results in the analyzed range are very important for radioprotection studies since the large part of broadcasting and mobile communication sources are located within it.

By using the data published in [13] it has been observed that, for Visible Human phantom, an empirical relationship holds for a 0.9 GHz plane wave exposure. It states that the whole body averaged SAR may be approximately calculated as 0.6 times the flux of the Poynting vector, times the minimal rectangular area circumscribing the largest coronal section of the body (it was illuminated frontally) and divided by the weight of the body.

By analyzing our phantoms, we found that the factor 0.6 is equivalent to the ratio between the area of the largest coronal section of the body and the minimal rectangular area circumscribing it. Then the above mentioned empirical relationship may be rewritten as:

$$SAR_{wb} \approx S \frac{A}{M} \quad \{1\}$$

where S is the power density in W/m^2 , A is the body area meant as the maximum cross section perpendicular to the wave number vector, and M is the mass of the body. This is not surprising, because it establishes that the power absorbed by the body is the Poynting flux by the section area; then this power distributes in the body and the averaged SAR is calculated dividing it by the body weight.

It is expected that this holds just at high frequencies where the absorption is eminently superficial. For this reason we report this approximated value only above 3 GHz in the graphs.

Since the computational burden involved in the calculation is rather high we could not provide results on a dense set of frequencies; thus, in case a fine structure were present in the spectrum, it would not be discriminated. However, it is probably unrealistic that a highly irregular behaviour in the SAR_{wb} would occur between a data point and the other one, even though they are rather sparse.

In [2] sub-resonances were seen slightly above 100 MHz for the sitting posture. Although we cannot confirm those results until a very dense set of frequency points will be available, we may draw some conclusions from the data here reported.

In the grounded state (as are the phantoms in the present study) main body resonance for the standing posture, occurs around 40 MHz. At 100 MHz, first point of our set, the tail of the resonance peak is still evident when the polarization is vertical in both orientations. It is more pronounced in the standing posture despite the sitting one has a shorter equivalent height and, consequently, a resonant frequency nearer to 100 MHz. Probably, since the shape of the body does not resemble anymore a linear antenna, the absorption is smeared on a larger, but less intense, resonance peak. It is also evident from the graphs that the peak is polarization-dependent: the SAR_{wb} is minimal at 100 MHz with horizontal polarization, which seems instead to show its maxima around 500 MHz or above.

Probably the most remarkable conclusion which can be drawn by the graphs is how good the very simple formula {1}, is able to provide an order-of-magnitude SAR_{wb} estimation above 500 MHz for both body orientations (frontal and lateral). The larger difference between the two body orientations is found for the standing posture, where the cross sectional area exposed to the wave almost doubles in passing from lateral to frontal orientation. Minor differences are instead visible for the seated case where the frontal cross section is diminished by the femurs' region with respect to the standing one.

These preliminary results suggest that, despite the roughness of formula {1}—which takes into account neither the dielectric properties of the body, nor its shape along the propagation direction—it gives reasonably good approximation of the SAR averaged over the whole body, at least above 500 MHz.

A conclusive statement about fulfilling of ICNIRP [14] limit can also be formulated: thresholds for whole body averaged SAR is 0.4 and 0.08 W/kg for occupational and general public, respectively. From that, the reference levels, under conservative assumptions, were calculated as: 10 and 2 W/m², till 400MHz, a linear connection follows up to 50 and 10 W/m² at 2 GHz and above this frequency values remain unchanged till 300 GHz. Scaling the SAR_{wb} to these limits allows the threshold of Figures 3 and 4 to be calculated. As it is shown in the graphs, the standing posture with frontal exposure and vertical polarization remain the conditions for which the absorption goes nearer to threshold although never reaching them.

Figure 3: Whole body averaged SAR (Poynting flux of 1 W/m²) for the sitting male phantom. In black and gray the frontal and lateral exposition, respectively. The polarization is vertical (solid lines) or horizontal (dashed lines). Approximated values are obtained by formula {1}. Dotted line is the scaled ICNIRP threshold which is applicable for both occupational and general public.

Figure 4: Whole body averaged SAR (Poynting flux of 1 W/m²) for the standing male phantom. In black and gray the frontal and lateral exposition, respectively. The polarization is vertical (solid lines) or horizontal (dashed lines). Approximated values are obtained by formula {1}. Dotted line is the scaled ICNIRP threshold which is applicable for both occupational and general public.

Abstract

The purpose of our experiments was to measure the effects of 1800 MHz microwave radiation on membrane anisotropy of a human blood monocitar and trombocitar cell population. Power level of the applied CW microwave radiation was low enough to consider it to be athermal. Experience demonstrates that the natural tendency to decrease of cell membrane anisotropy is favoured by microwave irradiation. This tendency maintains after the ceasing of microwave irradiation.

Introduction

Due to the extensive use of electromagnetic fields in everyday life, more information is required to detect the mechanisms of interaction and the possible side effects of microwave radiation on the structure and function of the organism. The target of these experiments was to find the effects of 1800 MHz microwave radiation on human cells. This frequency was chosen because it is used for the extension of mobile telephony systems. The biologic parameter followed in experiments was the membrane anisotropy of human blood monocytes and trombocytes.

Experimental method

Principle of the method

The membrane fluidity of irradiated and nonirradiated human blood cells was monitored by fluorescence anisotropy measurements of TMA – DPH labeled cells. Fluorescence anisotropy was measured before, during and after microwave irradiation of human blood monocytes and trombocytes.

The principle of the method consists in labeling the cellular membrane with a specific fluorescent dye. TMA – DPH with the formula shown in Fig.1 binds on the hydrophilic external surface of the cell membrane.

Fig.1. Formula of 1 - [4 - (trimethylammonium) phenyl] - 1, 3, 5 - hexatriene (TMA – DPH)

The biological sample is then illuminated with vertically polarized light.

Upon excitation of a molecule with vertically polarized light, the molecule will emit a fluorescent radiation more or less polarized, depending on the degrees of freedom of the molecule during the lifetime of the excited state. Depolarization degree of fluorescent light is a measure of the fluorophore freedom and therefore it is a measure of fluidity of the surrounding medium. Both the absorption and the emission of polarized light by a molecule are due to electronic transitions. A molecule can absorb a photon only if the molecular transition moment lies in the polarization plane of the exciting incident light. Reciprocal, when it comes back in the initial

status, the excited molecule emits light polarized in the plane of molecular transition moment. It follows that from a populations of molecules randomly oriented, illuminated with polarized light, only a sub-population will be excited (those with the molecular transition moment properly oriented).

An excited molecule will remain in this status only a small (some nanoseconds) time – naturally lifetime of excited status. After this time it will relax emitting polarized light in the manner described above. If during naturally lifetime of excited status the molecule changes its position (due to the thermal agitation) the emitted light will be in other direction than the absorbed exciting light. It follows that, naturally, the emitted light from this molecular population will have a polarizing index smaller than the incident light. The depolarizing degree is a measure of the freedom of movement of the molecules in the fluid, therefore a measure of the fluidity.

Usually, the incident light is vertically polarized and the measurement of the polarization of the emitted light are made in vertical (I_{VV}) and in the horizontal plane (I_{VH}) where the indexes v and h refers to the vertical, respectively horizontal polarizing plane.

The monitored parameter is the fluorescence anisotropy index r of the emitted light defined as:

$$r = \frac{I_{VV} - GI_{VH}}{I_{VV} + 2GI_{VH}} \quad (1)$$

where:

I_{VV} = recorded intensity of vertically polarized fluorescence light when excitation light is vertically polarized;

I_{VH} = recorded intensity of horizontally polarized fluorescence light when excitation light is vertically polarized;

G = correction factor depending on the fluorimeter used in measurements; it is due to the imperfection of the detection system and of monochromators.

$$G = \frac{I_{HV}}{I_{HH}} \cong 1 \quad (2)$$

where:

I_{HV} = recorded intensity of vertically polarized fluorescence light when excitation light is horizontally polarized;

I_{HH} = recorded intensity of horizontally polarized fluorescence light when excitation light is horizontally polarized;

The wavelength of excitation and emission light were $\lambda_{\text{excitation}} = 356 \text{ nm}$ and $\lambda_{\text{emission}} = 429 \text{ nm}$, respectively.

By measuring the depolarizing of the light emitted by this fluorescent material it is possible to evaluate the membrane fluidity. A high value of anisotropy means the stiffening of the membrane and inverse, a low value corresponds to a more fluid membrane.

The purpose of our experiments was, using the above exposed method, to measure the membrane anisotropy of a monocytic human blood cell population irradiated with 1800 MHz microwave radiation and to compare it with the membrane anisotropy of non-irradiated cells.

Biological material (blood platelets) used in experiments was taken over from two healthy human donors and separated by centrifugation. Labeling of the blood cell (monocytes and trombocytes) membranes was done in 5 μl of TMA – DPH stock solution (0.5 mM TMA – DPH in dimethylformamide – DMF) and 1 ml of cell suspension were added to 1 ml Ringier solution in a fluorimeter cuvette with dimensions $1 \times 1 \times 5 \text{ cm}^3$.

Microwave experimental setup

The experimental arrangement allows simultaneous application of the polarized light and of the microwave radiation. The microwave experimental setup, it is presented in Fig.2. It consists in a microwave generator followed by a variable attenuator and an isolator with the role to prevent the reflected waves to reach the emitting device. The microwave chain contains two 20 dB directional couplers mounted as in Fig.2 in order to measure the direct and reflected power traveling in setup. Via two identical detectors, two voltages proportional

with the direct and reflected microwave powers are displayed on the voltmeters (1) and (2). Prior the beginning of the experiments a calibration step is performed.

Fig.2. The microwave setup (a) and the applicator (b)

The radiating element is a $\lambda/2$ antenna (applicator) made using a semi-rigid cable. The external metallic shield of the cable was removed on a length of 12 mm (section AA') and the cable dielectric was removed on a length of 6 mm (section BB') exposing 6 mm of central conductor. The antenna is introduced in the container in such a manner that the exposed dielectric and the central conductor are totally submersed in the biological fluid (up to the section AA').

The microwave power level effectively injected in the biological sample is the difference between direct power level and reflected power level and minus the losses in cables and transitions.

Experiments and results

Experiments on human monocytes membrane anisotropy

From the power balance previously presented results a microwave power of approx. 70 mW CW effectively injected in the biological sample. Because the content of the mini-container is approx. 4 g of biological sample it results a SAR = 18 mW/g.

Anisotropy of monocyte membrane was measured for 90 min at time intervals of 5 min. In the first 30 min the microwave radiation was not applied so that the anisotropy variation in this time interval was considered as a measure for natural anisotropy decrease. In the next 30 min the biological samples were irradiated in the conditions presented above. Finally, for the last 30 min the microwave radiation was interrupted but the measurements continued at the same time interval of 5 min each in order to see the evolution of anisotropy following the irradiation.

The obtaining results are displayed in Tab.1 prior to, during and after the microwave irradiation. The normalization was made to the values of anisotropy at the beginning of the experiments. One can see that the natural tendency of anisotropy is to decrease (in the first 30 min) and this tendency is maintained during the irradiating session and also after the interruption of microwave application.

In order to have a better understanding of the microwave effects, a number of samples pairs were chosen following the criterion of closest values of the rate of the anisotropy decrease in the first 30 min (without microwave irradiation). One of the components of each pair was then irradiated with microwaves and the other was kept as reference. The rate of anisotropy decrease was measured during the microwave application and in the post-irradiation time.

The results for four pairs of biological probes are presented in Table 2. There is shown the difference between rates of the anisotropy decrease in the two biological samples in each pair. One may see an increasing rate of this parameter during the irradiation time, tendency maintained also in post-irradiation time.

TABLE 1
DECREASING OF THE ANISOTROPY (NORMALIZED VALUES)

Pre-irradiation		Irradiation		Post-irradiation

Experiments on human trombocytes membrane anisotropy

Experiments made using a trombocitar population obtained from human blood are similar with those concerning monocitar population. The same microwave irradiation setup was used. There are, nevertheless, some differences.

a) The experiments were made using two microwave power levels: 7 mW and 60 mW, meaning SAR values of 1.75 mW/g and respectively 15 mW/g.

b) The total experimental time was 3 h, each measurement being made at 5 min time interval. The microwave irradiation was applied in the second hour of the experiment (between minutes 60 and 120).

c) In each day was made an experiment using the same trombocitar concentrate. There were four experiments in four days but, for the sake of space saving, only the results of first two experiments are presented. The other results are very similar.

The power levels are done at the point (a).

The values of anisotropy obtained in these experiments are presented in Table 3 and the graphs representing these values are presented in Figs. 7 – 10.

TABLE 3

Conclusions

In the above presented experiments power level of the applied microwave radiation was low enough to consider it to be athermal. From the numerical data and the drawings presented in this paper one may conclude the following:

- a) During the experience (with or without microwave irradiation) the tendency of anisotropy of human blood monocytes membrane anisotropy is to decrease;
- b) This decrease is greater when 1800 MHz microwave radiation is applied. This tendency is maintained after the ceasing of microwave irradiation.
- c) For a better emphasizing of this result, for monocytes cellular population, samples pairs of blood samples were chosen following the criterion of closest values of the speed of the anisotropy decrease in the first 30 min. The speed of the anisotropy decrease was evaluated in the time and after the microwave irradiation. The result is presented in Table 2 and in Figs 1 and 2, showing the same effect on the speed of anisotropy decrease.
- d) For a population of trombocytic cells, the anisotropy of the cellular membrane, also, decrease both during and after ceasing of the microwave radiation..
- e) The slope of the decreasing curve is greater after irradiation with 60 mW microwave radiation. It seems like RF radiation favours the decrease rate of membrane anisotropy.

Abstract

The aim of the study was to assess the long-term effects of electromagnetic radiation (EMR) on cardiovascular system of medical staff in physiotherapies. 52 exposed subjects (4 male and 48 female; aged 47.3 ± 8.7 yrs.) and a control group of 52 subjects, matched by sex and age, with similar job characteristics except for EMR were studied. The EMR exposure from appliances emitting at 50 Hz, 150 kHz, 27.12 MHz, 2.45 GHz was assessed. The workload and psychosocial factors were followed, too. The cardiovascular risk factors arterial pressure, lipid profile, body mass index, waist/hip ratio, smoking, alcohol consumption, nutrition, family history of cardiovascular disease were studied. The incidence of hypertension was moderate with the studied physiotherapists (26.9 % v.s. 23.8 % with the control group). The total cholesterol (TC) and low-density lipoprotein cholesterol (LDL-C) were significantly higher in the exposed group. The odds ratios indicate higher chance of becoming dyslipidemic with the exposed to EMR subjects [for TC OR (95 % CI) = 1.570 (1.048 – 2.351) and for LDL-C OR (95 % CI) = 1.840 (1.158 – 2.924)]. In conclusion, our data show that the EMR exposure of the medical staff in physiotherapies is associated with the adverse effects on cardiovascular system.

Key words: Arterial hypertension, dyslipidemia, EMR exposure, long-term effects, health risk

Introduction

Physiotherapists are exposed to many risks in their work environment, some common for the health care workers, and some specific for the profession, such as the exposure to electromagnetic radiation (EMR), emitted from pulsed magnets, d'Arsonvale devices, equipment for microwave and high frequency diathermy, optical sources (UV, IR and visible), lasers. Some of the devices emit electromagnetic radiation above the exposure limits, rising health concerns.

The general health status of physiotherapists is largely unknown (Cromie et al. 2002), but some studies suggest possible adverse health effects of the EMR exposure, including increased risk of cardiovascular diseases. Hamburger et al. (1983) found positive relation between the EMR exposure and heart disease in physiotherapists, but in the study the exposure was categorized as either high or low on the base of mean number of employed years and mean number of treatments delivered by week. More attention has been paid to the health risks of radiofrequency EMR exposures in communications, but there still exist controversies concerning the effects of long-term exposures to low-level EMR (recent reviews Repacholi, 1998, Krewski et al. 2001, Vangelova and Deyanov 2003. Jauchem (1997) reviewed the epidemiological studies with a general conclusion that they had not yielded any obvious cardiovascular related hazards on long-term low-level exposures, in spite of the presence of various physiological effects. Our earlier data showed high rate of hypertension in broadcasting and TV station operators (Israel and Tomov, 2000). A second study was carried by our group in 49 broadcasting and 61 TV station operators (Vangelova et al. 2006) in order to confirm the previous findings, enlarged with serum lipids, and showed significantly higher chance of becoming hypertensive and dyslipidemic in broadcasting and TV station operators exposed to radiofrequency EMR. Slight, subclinical ECG abnormalities, accompanied by symptoms of sympathicotony in heart variability, shifts in the diurnal rhythms of blood pressure and heart rate in 77 AM broadcasting station operators (0.7-1.5MHz) were reported (Bortkiewicz, 1995; Szmigielski, 1998). Szmigielski (2000) confirmed the above data in a study on 38 workers in radio transmitting centers, exposed to 10-30 MHz EMF.

The aim of the study was to assess the long-term effects of EMR on the cardiovascular system of medical staff in physiotherapies.

Material and methods

The cardiovascular risk was assessed in 52 physiotherapists (4 males and 48 females) working with EMR emitting devices of age 47.3 ± 8.7 years and length of service 23.0 ± 9.5 years. A control group of 52 subjects from the same hospitals were examined, matched by sex, age and shift work schedules, with similar job characteristics except for the EMR. Their age was 47.8 ± 8.5 and length of service of 21.6 ± 4.6 years. The investigated subjects signed an informed consent.

EMR exposure assessment

There are a variety of sources of EMR in physiotherapies, emitting in the frequency range from constant fields ($F = 0$ Hz) to optic radiation. This puts substantial difficulties to the elaboration of a precise workplace exposure assessment, complicated by variety of situations in different cabinets, number of patients, etc. The scope of the devices in the studied units is the following:

- Devices for local thermotherapy (“Chinese vacuum cleaner” – Qi Gong);
- Equipment for galvanotherapy, ion - galvanotherapy and electrostimulation, “bipulsator” (for therapy with electric pulses), diadynamic;
- Devices for local franklinization – “ion shower”;
- Equipment for low frequency diathermy, diathermal ion galvanization and diathermal electrostimulation;
- D’Arsonvale devices;
- Equipment for treatment with magnetic/electric field within the radiofrequency (RF) range (27.12 MHz), and with microwaves (2,45 GHz) for inductive-thermal therapy;
- Microwave electropexia;
- Devices for photo-therapy:
 - Solariums;
 - UV lamps for individual UV therapy;
 - UV sources application of the PUVA method of therapy;
 - Lamps of types “SOLUX” and “INFRAROUGE”;
 - Laser diodes, gas lasers and other sources of coherent light.

We used the approach of individual assessment of EMR in physiotherapies, described earlier (Israel and Tschobanoff, 2006). In order to establish unified conditions for exposure assessment for different frequencies (over the overall frequency range) we applied a general unified indicator associated with the energetic irradiation dose, according to the ICNIRP Guidelines (1), ACGIH TLVs (2), and the Bulgarian National Standards (3, 4).

The energy load of the human organism is defined for three cases as a derived quantity of energy falling at external irradiation: W_E , W_H and W_S , based on dispersed energy per time unit on human body during the official working shift. Measurable quantities are used – intensities and power density according to the distance from the generator to the measuring device and the respective frequency range of the single photon.

SAR is the specific value of power absorbed by the recipient; **SA** is the specific value of the respective absorbed energy according to the calculated **SAR**.

As **SAR** is introduced by the dimension of base metabolism of an adult man (175 cm/70 kg) the dimension of **SA** is the dimension of **SAR** by the time, that is

$$SA = SAR \cdot t \quad [J / kg]$$

The two types of quantities - W_E , W_H and W_S on the one side, and **SAR**, **SA** on the other do not differ substantially in conditions of air equivalent environment and a human body situated in it.

SAR is introduced through Human Equivalent Antenna. If the respective effective area is A_e , then through relationships between the dimensions of the quantities **W** and **SA** following by the definition for power and from the way of determining human body exposure, the quantity **W** corresponds to whole body value of **SA** at constant body weight and unchanging mean conductivity of the tissue, standardized to the effective exposure area A_e . The magnitude of the latter on its part depends on the mutual orientation of a standing person and the intensity of the falling electric field E .

The measurable quantity in all cases is the same – E [V/m]. Consequently W_E will incorporate the definition of **SA** and vice versa.

The exposure duration: real exposure time at work with a device T_{app} [h], followed by chronometer measurements, and a total duration of the working shift T [h] were registered. The duration time is introduced by the number of devices and the number of patients serviced by the individual.

The method was unified for the equipment, the distances to the particular device and the mandatory restrictions to the behavior of the physicist/engineer, performing the measurement. The major characteristics of the method are the 6 mandatory distances to the different types of generators determined depending on the frequency range of the radiation. They conform to the requirements for measurement in the far and near field zones and the requirements for determination of **SAR** in different cases of electromagnetic energy falling on a standing human.

The dose as a function of the squared mean measured intensity was presented by the **SAR** quantity. Our calculation formulation were based on the vision of the averaged dose: the dose (calculated with the actual measured values of the field and exposure time) multiplied by the mean geometric value of the partial doses on the distance from the physician/nurse to the patient r_i and the dose of the same to another characteristic distance (one of the cited – r_i , $i \neq 1$). Thus a characterizing quantity was obtained which is a non-dimensional growing sum \bar{D} :

$$\bar{D} \approx \sum \frac{1}{q} \sqrt{D(r_1)} \sqrt{D(r_{i \neq 1})}$$

Here $1/q$ was a non-dimensional quantity – ratio.

The squared field strength (E^2) used for the dose assessment was equal to the product of the measured intensity of the field at distance r_1 and the sum of weighed intensities of the other 5 distances. The method allows, at unified measurements, the elaboration of individual exposure assessment for each person in physiotherapy through calculations depending on the number of devices, number of patients and the actual configuration of the ward.

Physiotherapy devices and calculated values of the exposure for every device/for one person of the personnel were as follows:

1. Device “Megatherm”:

$SAR \leq 3.71 \text{ W/kg}$

$f = 27.12 \text{ MHz}$; basic restrictions (*br*) for whole body SAR : $SAR_{br} = 0.4 \text{ W/kg}$

2. UHF acoustic generator for ultrasound therapy: $f \leq 2.5 \text{ MHz}$:

(measurements in the frequency range $f \leq 2 \text{ kHz}$)

$$j \approx 3.8 \text{ mA/m}^2$$

$f \leq 2 \text{ kHz}$; basic restrictions for the induced current: $j_{br} \leq 2 \text{ mA/m}^2$

3. UHF 66 (Russia):

$SAR \leq 9.8 \text{ W/kg}$

$f \leq 2 \text{ kHz}$; basic restrictions for the induced current: $j_{br} \leq 2 \text{ mA/m}^2$

4. Magnet N 80 (Bulgaria):

$$j \approx 0.31 \text{ A/m}^2$$

5. Magnet NM (Bulgaria):

$$j \approx 0.28 \text{ A/m}^2$$

Light sources (polychromatic):

restrictions according to ACGIH (2004):

IR: $S \leq 1.8 \cdot t^{-3/4} \text{ W/cm}^2$ (for cornea and lens)

IR: $S \leq 0.6/\alpha \text{ W/cm}^2 \cdot \text{sr}$ (for retina protection)

IR (with blue light filter – B1): $1 \mu\text{W/cm}^2$, and : $t_{\max} \leq 10 \text{ mJ/cm}^2/\text{S}$

UV and visible light: $t_{\max} \leq 0.003 \text{ J/cm}^2/\text{S}$

6. Quartz (UVB-1, UVB, UVA, Visible:

$$S \approx 17.6 \text{ mW/cm}^2$$

7. Solux Infrarouge, without filters:

$$S \approx 286.1 \text{ mW/cm}^2$$

8. Solux Infrarouge, with filter B1:

$$S \approx 4.9 \text{ mW/cm}^2$$

9. Interferenz - Endovak:

$$j \approx 0.69 \text{ A/m}^2$$

$f \leq 100 \text{ kHz}$; basic restrictions for the induced current: $j_{br} \leq 1 \text{ A/m}^2$

10. Diodynamik (Bulgaria):

$$j \approx 0.15 \text{ mA/m}^2$$

11. Galvanostat (Bulgaria):

$$j \approx 0.15 \text{ mA/m}^2$$

$f = 150 \div 300 \text{ kHz}$; basic restrictions (br) for whole body SAR: $\text{SAR}_{br} = 0.4 \text{ W/kg}$

12. D'Arsonval:

$\text{SAR} \leq 0.4 \text{ W/kg}$

$f = 27.12 \text{ MHz}$; basic restrictions (br) for whole body SAR: $\text{SAR}_{br} = 0.4 \text{ W/kg}$

13. UHF 66 (Russia):

$\text{SAR} \leq 9.8 \text{ W/kg}$

$f = 2450 \text{ MHz}$; basic restrictions (br) for whole body SAR: $\text{SAR}_{br} = 0.4 \text{ W/kg}$;

for limbs $\text{SAR}_{loc} = 20 \text{ W/kg}$

for head $\text{SAR}_{loc} = 10 \text{ W/kg}$

14. Radarmed (2 devices):

with symmetric applicators

$\text{SAR} \leq 0.31 \text{ W/kg}$

with conical applicator

$\text{SAR} \leq 5.3 \text{ W/kg}$

Light sources (polychromatic):

restrictions according to ACGIH (2004):

IR: $S \leq 1.8 \cdot t^{-3/4} \text{ W/cm}^2$ (for cornea and lens)

IR: $S \leq 0.6/\alpha \text{ W/cm}^2 \cdot \text{sr}$ (for retina protection)

IR (with blue light filter – B1): $1 \mu\text{W/cm}^2$, and : $t_{max} \leq 10 \text{ mJ/cm}^2/\text{S}$

UV and visible light: $t_{max} \leq 0.003 \text{ J/cm}^2/\text{S}$

The relative values for the whole frequency range in each physiotherapy were calculated and the obtained quota was much larger than 1.

Confounding factors as noise, microclimate and psychosocial factors were followed and showed no differences between the groups.

The cardiovascular risk was assessed on the base of arterial pressure, lipid profile, body mass index (BMI), waist circumference, smoking habits, family history for cardiovascular disease, etc. The arterial pressure was measured with Hg sphygmomanometers two times in a period of three months. The hypertension was defined using the JNC VI (1997), as well as preliminary physicians diagnosis. Weight, height and circumferences at the narrowest part of the waist were recorded, and the BMI was calculated.

Blood for analysis was obtained after an overnight fast. The lipid profile included the following indices: total cholesterol (TC), high density lipoprotein cholesterol (HDL-C), low density lipoprotein cholesterol (LDL-C), triglycerides and TC/HDL-C ratio. The assessment of the lipid indices was performed with enzymatic tests. The HDL was separated by precipitation of LDL and VLDL and the cholesterol was assayed in the HDL fraction. The LDL-C was calculated using the formula of Friedewald for triglycerides $< 4.3 \text{ mmol/l}$. The ratio TC/HDL-C was calculated, too.

The data were analyzed using SPSS software. Analysis of variance (one-way ANOVA), correlation analysis, χ^2 and odds ratio were applied.

Results

The incidence of hypertension was moderate in the medical staff and did not differ significantly between the studied groups (26.9 % with the staff exposed to radiofrequency EMR v.s. 23.8 % with the control group). No significant differences both in systolic and diastolic blood pressure (SBP and DBP) were found between the exposed group in comparison to the control one (Table 1). The BMI did not significantly differ between the studied groups, but the waist was slightly higher with the exposed group. The TC, HDL-C and LDL-C were significantly higher in the radiofrequency EMR exposed group with comparison with the control group.

CARDIOVASCULAR RISK IN PHYSIOTHERAPISTS

Table 1.

The blood pressure, anthropometric and metabolic variables of medical staff from physiotherapies, exposed to EMR and control group

Indices/Groups	Medical staff from physiotherapies	Control group
SBP (mmHg)	124.8 ± 19.7	122.4 ± 16.2
DBP (mmHg)	80.2 ± 12.6	78.2 ± 8.5
BMI (kg/m ²)	24.5 ± 3.8	23.3 ± 3.6
Waist (cm)	83 ± 11.9	81.5 ± 11.1
TC (mmol/l)	5.44 ± 1.06**	4.97 ± 0.69
HDL-C (mmol/l)	1.53 ± 0.28*	1.39 ± 0.34
LDL-C (mmol/l)	3.42 ± 0.91**	3.07 ± 0.70
Triglycerides (mmol/l)	1.23 ± 0.71	1.19 ± 0.57
TC/HDL-C ratio	3.64 ± 1.02	3.57 ± 0.87

* p < 0.05; ** p < 0.01

The rate of distribution of some of the main cardiovascular risk factors is presented in Table 2. Significantly higher rate TC > 5.2 mmol/l and LDL-C > 3.4 mmol/l was found with the exposed to EMR medical staff, with higher significance for LDL-C. The odds ratios indicate higher chance of becoming dyslipidemic with the exposed to EMR subjects [for TC OR (95 % CI) = 1.570 (1.048 – 2.351) and for LDL-C OR (95 % CI) = 1.840 (1.158 – 2.924)].

Table 2.

The frequency of distribution of the main cardiovascular risk factors in medical staff from physiotherapies, exposed to EMR and a control group.

Indices	Medical staff from physiotherapies	Control group	χ^2	Corrected χ^2	P
TC > 5.2 mmol/l	59.6 %	36.5 %	5.254	5.200	.018
HDL-C < 1 mmol/l	14.9 %	28.8 %	2.781	2.752	NS
LDL-C > 3.4 mmol/l	55.3 %	26.9 %	8.267	8.183	.004

The rate of smoking was high in both studied groups, slightly higher in the control one (44.2 % v.s. 40.4 % in the medical staff from physiotherapies). There were no considerable differences in the self reported degree of smoking (33.3 % of the medical staff from physiotherapies smoked 5-10 cigarettes/day, 57.1 % smoked 10-20 cigarettes/day and 9.5 % more than 20 cigarettes/day while in the control group 39.1 % smoked 5-10 cigarettes/day, 47.8 % smoked 10-20 cigarettes/day and 13 % more than 20 cigarettes/day). 47.6 % of the medical staff from physiotherapies smoked for more than 20 years v.s. 43.5 % of the control group. There was no difference in the proportion of self reported drinkers between the investigated groups, nor in the number of beverages per week among the alcohol users. The self reported nutrition habits and physical activity during the free time did not differ between the groups, too.

Discussion

Our data show higher rate of dyslipidemia with the exposed to EMR physiotherapists, thus supporting the findings of Hamburger et al. (1983) for positive relation between the EMR exposure and heart disease in physiotherapists and confirming the data for higher rate of dyslipidemia under EMR exposure in other occupational groups as broadcasting and TV transmitting operators (Vangelova et al. 2006). The greater chance of becoming dyslipidemic of the physiotherapists exposed to EMR was confirmed by the calculated odds ratio. We suppose that the variations of TC and LDL-C were mediated to some extent by the stress system. Our data show significant EMR exposure-effect on the excretion rates of stress hormones in physiotherapists (Israel et al. 2006) and in other occupational groups (Vangelova et al., 2005). The elevation of stress hormones under

occupational stressors has been shown to interact with cardiovascular risk factors (Rosmond 1998, Fraser et al. 1999, Vrijkotte et al. 1999, Chrousos, 2000).

The higher rate of dyslipidemia in the medical staff from physiotherapies can be associated mainly with the EMR exposure as the confounding factors as noise, microclimate, work organization, work control, work content, etc. were controlled (unpublished data), and the studied subjects had the same social class, found to be an important confounder (Boggild et al., 1999b). Although our study was controlled we do not exclude some synergistic effects of EMR with other occupational stressors, as emotional load of dealing with patients, work tasks requiring intense concentration, a feeling for risk of infections, strain, etc.

The rate of hypertension was similar in the exposed to EMR and control group medical staff for difference of earlier findings for higher rate of hypertension in broadcasting and TV transmitting operators working under radiofrequency EMR (Bortkiewicz 1997, Israel and Tomov, 2000, Vangelova et al. 2006). There are several differences between the cited previous studies and the present one. First, the EMR exposure was different. The physiotherapists were exposed for very short periods of time to high intensities, while the studied broadcasting and TV transmitting operators were exposed during all the working time, but with lower intensities. Second, the job task was quite different. The broadcasting and TV transmitting operators work was monotonous, while the job task of physiotherapists was mobile, associated with emotional load of dealing with patients. Third at the last, but not at the least of importance, the broadcasting and TV transmitting operators groups consisted mainly of males, while the medical staff from physiotherapies were mainly females. So the gender differences might contribute to inconsistency of the results concerning hypertension. There are data that the impact of stress is greater on arterial pressure in men and on indices associated with insulin resistance, as lipid profile indices, in females (Chrousos, 2000).

The body mass index did not differ between the groups, but the medical staff from physiotherapies had more centrally disposed adipose tissue, well known risk factor for cardiovascular disease (CVD). The rate of smoking was high in the two studied groups, slightly higher in the control one. The differences in the self reported degree of smoking and the duration of smoking between the studied groups were negligible. No differences of self-reported alcohol consumption, nutrition habits, physical activity were found.

Summing up, our data suggest that the medical staff exposed to EMR was at greater risk of becoming dyslipidemic. Further studies are needed to investigate the effect of EMR on cardiovascular risk factors in the medical staff in physiotherapies, using an approach of studying the personal long-term EMR exposure in order to reach better understanding of the possible adverse effects of EMR on cardiovascular system.

RF-ABSORPTION AND TEMPERATURE ELEVATIONS IN THE INNER EAR AND THE EYE DUE TO EXPOSURE FROM HANDHELD DEVICES IN THE 400 MHz TO 1850 MHz RANGE

G. SCHMID¹, R. ÜBERBACHER¹, T. SAMARAS²

¹ARC SEIBERSDORF RESEARCH GMBH, A-2444 SEIBERSDORF, AUSTRIA

ABSTRACT

In order to allow detailed numerical RF dosimetry and computation of RF-induced temperature elevations in small anatomical structures, numerical models of the human eye and the inner ear organs (cochlea, labyrinth, auditory nerve, hearing bones) were developed based on frozen section techniques at a spatial resolution of 0.1 mm. After inserting these high resolution models into a commercially available head model, FDTD computations of SAR distribution and temperature elevations due to RF absorption were carried out using the SEMCAD X simulation platform. Generic models of handsets at 400 MHz, 900 MHz and 1850 MHz, operated in close proximity to the head, were considered as radiation sources.

Due to the heterogeneity in the area of the cochlea and the labyrinth (actually comprising highly conductive liquids surrounded by compact bone), the results showed a highly heterogeneous SAR distribution and SAR-peaks inside the cochlea and the labyrinth. However, temperature computations showed, that temperature elevations inside these organs are well below 0.1°C, when considering typical output power values of handheld devices (maximum for 400 MHz exposure).

In case of frontal exposure maximum temperature elevations in the eye of approximately 0.6°C were found for typical device output powers.

I. INTRODUCTION

The analysis of RF-power absorption and RF-induced temperature elevations in the human head, caused by handheld mobile communication devices, has been investigated in numerous scientific publications in recent years (e.g. [1]-[18]). In most cases computational techniques based on the Finite Difference Time Domain (FDTD) method were used for solving both the electromagnetic and the thermodynamic problem; the latter was mostly described by the Pennes' *Bioheat Transfer Equation* (BHTE) [19]. However, a detailed quantitative comparison of the results reported by these studies is difficult because of the variety of considered exposure situations and RF-source power levels, as well as the different head models used, which significantly affect the correlation between mass averaged Specific Absorption Rate (SAR) in the head and the temperature increase in specific tissues, as reported by [10]. When relating the temperature increase to the maximum 10g averaged SAR in the head, the reported maximum temperature elevations in brain tissue are ranging between approximately 0.05°C/(W/kg) and 0.16°C/(W/kg). Concerning eye exposure, plane wave irradiation was considered in most cases in the past, mainly at frequencies beyond 1 GHz. Relating the maximum temperature increases in the eye found by these studies to the incident power density, the reported values are ranging between 0.003 °C/(W/m²) and 0.006°C/(W/m²).

The original spatial resolution of the numerical head models used in the above mentioned studies was usually not better than approximately 0.5 mm in horizontal direction and 1-2 mm in vertical direction (except [18], which were using 0.25 mm resolution for the eye). Due to this fact, anatomically small structures like the inner ear organs are, if at all, not accurately represented in these head models. Consequently, no detailed analysis of RF absorption in these organs and structures was possible so far.

In order to enable detailed RF dosimetry in the inner ear organs and in a detailed model of the eye, numerical models of the inner ear and the eye at a spatial resolution of 0.1mm x 0.1mm x 0.1mm were developed in this study and first results regarding RF-absorption and temperature elevations caused by generic phone models in the frequency range 400 MHz – 1850 MHz are presented.

II. MATERIAL AND METHODS

II.1. High resolution anatomical models of the inner ear and the eye

For developing the numerical model of the inner ear, vertical slices at a separation distance of 0.1 mm of a section of the left hemisphere of a real male human head (provided by the Center for Anatomy and Cell Biology, Medical University of Vienna) were obtained by frozen section technique (figure 1).

Each slice was scanned at a resolution of 1200 dpi using a commercially available document scanner (HP ScanJet 3970). Based on these digital images the segmentation (0.1 mm x 0.1 mm) of the *cochlea*, the *vestibulum*, the *canales semicirculares*, the *auditory ossicles* and the *tympanic membrane* as well as the conversion into a SAT-File format was carried out by IT'IS Foundation, Zurich, Switzerland. Exactly the same procedure was used for the development of the eye model, where *cornea*, *sclera*, *lens* and the optic nerve were distinguished during segmentation.

Figure 1: Examples of vertical cross sections through the human inner ear

Using the FDTD-based simulation platform SEMCAD X, the developed high resolution models of the inner ear organs and the eye were then inserted into a commercially available male head model based on the visual human data set (0.5 mm x 0.5 mm horizontal, 2 mm vertical resolution, 47 different tissue regions). In case of the inner ear model, the tympanic cavity, the external auditory canal as well as the auditory nerve were added by manual modeling and adjusted correspondingly in order to have an anatomically correct representation (figure 2). The yellow colored structure in the close-up view in figure 2 corresponds to the inner space of the labyrinth (cochlea, vestibulum, semicircular canals), which is filled with approximately 200 μ l of perilymph- and endolymph-liquid. This structure is embedded in the highly compact petrous bone. In case of the eye model the lens' nucleus was added manually (figure 3).

Figure 2: Anatomically correctly positioned high resolution inner ear organs inside a commercially available numerical head model

Figure 3: High resolution eye model in 3D view (top) and in a horizontal cross section (bottom)

II.2. Considered exposure conditions

Three different generic models of handsets, one per frequency, were considered as radiation sources. At 400 MHz a resonant helix antenna (axial length 61 mm, helix diameter 8.6 mm, wire diameter 1 mm, 14 turns) on top of metallic box (130 mm x 50 mm x 30 mm) was considered as a representative model for a hand held radio set such as used for example in a TETRA system. For 900 MHz and 1850 MHz quarter wave

SAR AND TEMPERATURE INCREASE IN SMALL ORGANS INSIDE THE HEAD

monopoles (diameter 2 mm) on top of a metallic box (100 mm x 40 mm x 20 mm) were chosen as representatives for mobile phones of the GSM900 and the DCS1800 and UMTS systems, respectively. For each radiation source lateral exposure in “Tilt” position as well as frontal exposure with a distance between the antenna’s feedpoint and the left eye of approximately 2.5 cm were considered. Figure 4 shows the 6 different exposure conditions.

Figure 4: Considered exposure conditions. left: lateral exposure in “tilt” position at 400 MHz, 900 MHz and 1850 MHz, right: frontal exposure at 400 MHz, 900 MHz and 1850 MHz

II.3. Computational techniques used

The FDTD based SEMCAD X simulation platform was used for both the electromagnetic as well as the thermodynamic computations. The used thermodynamic solver was based on Pennes’ BHTE and both the electromagnetic as well as the thermodynamic computations were carried out on the same FDTD grid, using a graded mesh with mesh size between 0.25 and 5 mm. However, in the irradiated hemisphere the maximum grid step was kept below 1.5 mm and constant at 0.25 mm in the region of the high resolution models of the inner ear region and the eye. This resulted in a total of approximately 20-25 million FDTD cells, depending on the considered source model.

II.4. Tissue parameters and boundary conditions

For the dielectric properties of the tissues values according to [20] were taken. With respect to the thermal properties 19 different materials were allocated to the more than 50 different tissue regions in the head model (including the high resolution inner ear and eye). Table 1 lists the used thermal properties, which were derived from several sources in the literature (e.g. [1],[13],[21]).

Table 1: Thermal tissue properties used

material	density [kg/m ³]	specific heat [J/kg.K]	thermal conductivity [W/m.K]	perfusion [ml/min.kg]	metabolic heat [W/kg]
blood	1060	3780	0.51	10000	0
bone	1850	1300	0.39	11.5	0.15
brain average	1040	3650	0.55	608.5	9.70
cartilage	1100	3521	0.46	50	0.18
cerebellum	1040	3670	0.55	510	9.70
cerebrospinal fluid	1005	4116	0.59	0	0
cornea	1076	3793	0.52	38	0.32
fat (not infiltrated)	920	2493	0.24	25.3	0.15
gland tissue	1040	3600	0.53	3059	9.79
grey matter	1040	3684	0.57	608.5	9.70
lens	1080	3133	0.43	0	0
marrow	1020	3120	0.32	219	5.50
muscle	1045	3580	0.5	26.6	0.67
nerve tissue	1040	3582	0.46	37.7	9.61
skin dry	1140	3600	0.37	86.6	0.18
skin wet	1140	3600	0.37	86.6	0.18
tongue	1045	3580	0.5	26.6	0.67
vitreous humor	1003	3997	0.59	0	0.34
white matter	1040	3611	0.5	262.5	9.70

At the thermal boundary between the head model and the ambient a heat transfer of $8 \text{ W}/(\text{m}^2\text{K})$ at a nominal ambient temperature of 25°C was assumed. Thermal boundaries between air filled cavities inside the head model and their bounding tissues were assumed to be $4 \text{ W}/(\text{m}^2\text{K})$ at 37°C , except for the nasal cavity and the ear channel, where $30 \text{ W}/(\text{m}^2\text{K})$ at 35°C and $6.3 \text{ W}/(\text{m}^2\text{K})$ at 35°C were chosen, respectively.

III. RESULTS

Lateral exposure

Figure 5 depicts the distribution of SAR (not averaged, normalized to 1W radiated power) in a cross section of the head through the cochlea for all three frequencies considered. With respect to the inner ear, relatively high local SAR values appear inside the peri-/endolymph-filled labyrinth compared to the surrounding bone, especially at 400 MHz. This is due to the relatively high conductivity of peri-/endolymph, which is very similar to cerebrospinal fluid. In the last row of figure 5 the SAR distribution on the surface of middle- and inner ear organs (labyrinth, auditory nerve, tympanic membrane, auditory ossicles, compare figure 2) is shown.

Figure 5: SAR distributions (not averaged, normalized to 1W source power) in a cross section of the head through the cochlea for 400 MHz (left column), 900 MHz (center column) and 1850 MHz (right column). At the bottom the SAR distribution on the surface of the middle- and inner ear organs is shown.

SAR AND TEMPERATURE INCREASE IN SMALL ORGANS INSIDE THE HEAD

Despite of the inhomogeneous distribution of SAR inside the head, the thermodynamic computations show only very low temperature increases in it. Figure 6 illustrates the maximum temperature elevation in specific tissues, within the time period from switching on the radiation until thermal equilibrium is reached (after approx. 20 minutes). Note that the values in figure 6 are normalized to the case of a 10g averaged SAR of 2 W/kg in the head, i.e., the limit for localized exposure according to [22] and [23].

Figure 6: Maximum temperature elevation in specific tissues and organs due to a lateral exposure according to the current limit for localized exposure according to [22] and [23].

As it can be seen from the figure maximum temperature elevations are highest for 400 MHz due to the high penetration depth and the more homogeneous heating of the head, which causes lower temperature gradients and therefore less effective heat conduction inside the head. However, the absolute values of the obtained temperature elevations are rather small. They are below 0.05°C for grey matter, below 0.025°C in the inner ear organs and below 0.01°C in deep brain tissues. More superficial tissues as bone, muscles, fat and the skin on the head showed an increase in temperature between 0.1°C and 0.25°C. The absolute maximum temperature increase was obtained in the skin of the pinna and was approximately 0.9°C.

Front exposure

The distribution of SAR in case of having the radiation source in front of the left eye is shown in figure 7. Non averaged SAR values, normalized to 1 W radiated power are shown in a horizontal cross section of the head through the eye.

Figure 7: SAR distributions (not averaged, normalized to 1W source power) in a cross section of the head through the eye for 400 MHz (left column), 900 MHz (center column) and 1850 MHz (right column).

RF absorption in the eye increases with frequency and at 1850 MHz a “standing wave pattern” with a SAR maximum approximately in the center of the eye can be observed. This is due to the fact that at 1850 MHz the eye diameter is approximately one wavelength (in tissue) of the radiation frequency.

The maximum temperature elevations in specific tissues, within the time period from switching on the radiation until thermal equilibrium is reached (after approx. 20 minutes) are depicted in figure 8. Again the given values are normalized to the case of a 10g averaged SAR of 2 W/kg in the head.

Figure 8: Maximum temperature elevation in specific tissues and organs due to a frontal exposure according to the current limit for localized exposure according to [22] and [23].

Although the highest peak SAR values in the eye were obtained for the high (1850 MHz) frequency, the maximum temperature elevations appear again for a 400 MHz irradiation. The absolute maximum temperature elevation was observed in the lens and was approximately 0.6°C. Maximum temperature elevations in other (superficial) tissues are approximately in the same order of magnitude, ranging from 0.2°C to 0.6°C. In the optic nerve and in grey matter tissue temperature elevations up to approximately 0.25°C and 0.09°C were found, respectively. Interestingly, the temperature elevations in the middle and inner ear regions appear somewhat higher during frontal exposure compared to the case of lateral exposure. This effect, however needs to be investigated further, because it might be affected by the different spatial discretizations of the computation domain used for frontal and lateral exposure.

Influence of perfusion and ambient temperature

In order to estimate the impact of variations in the ambient temperature and in blood perfusion, computations (at 400 MHz) were carried out with tissue perfusion (all tissues) reduced to 50% of the nominal values listed in table 1, and an ambient temperature of 35°C (instead of a nominal value of 25°C). All other parameters remained unchanged. The results clearly show that for tissue regions deep inside the head a change in ambient temperature does not play an important role, whereas a reduction of perfusion by 50% increases the observed maximum temperature elevations by up to a factor of 2.5 in these tissues. For more superficially located tissues (skin, cartilage, fat, subcutis, bone) both perfusion as well as ambient temperature play a role with respect to the maximum temperature elevation.

Pulsed radiation

Current safety standards, e.g. [22], define the basic restriction for localized exposure in terms of a 6 minute average SAR. This means that for shorter times higher temporal peak SAR values are allowed. Therefore we investigated (at 400 MHz) the effect of pulsed radiation by applying short exposure peaks (in terms of 10g averaged SAR) of 4 W/kg, 12 W/kg and 72 W/kg for 180 s, 60 s and 10 s within a continuously repeated 6 minute interval, respectively. All of these cases lead to a 6 minute average SAR of 2 W/kg. The comparison of the pulsed exposure with a continuous wave exposure at 2 W/kg showed increased maximum temperature elevations for the mentioned kind of pulsed exposure. Tissues deep inside the head were significantly more affected by this effect than superficial tissues. The worst of the considered cases was the repeated 10 s / 72 W/kg lateral exposure, which, for example, leads to a relative increase of the maximum temperature elevation in the skin by a factor of 2 compared to a factor of 11 in the hypothalamus.

IV. CONCLUSION

In general, the obtained results showed that for exposure situations typical for usage of modern digital mobile phones the RF-induced temperature elevations inside the head are rather small. Although a very heterogeneous pattern of RF power dissipation could be observed due to the significantly different dielectric properties of the different tissues, no temperature “hot spots” are to be expected due the efficient heat transfer mechanisms taking place in the tissues (heat conduction and heat transfer by perfusion). As far as comparable, when relating the maximum temperature elevations to the 10g averaged SAR in the head, our results are in line with results reported by other authors ([1]-[18]), even though our results appear to be at the lower end of the range of RF-induced temperature elevation stated in [1]-[18]. This might be caused by the specific properties of the used head model (based on the visual human data set) with respect to its tissue composition [10].

The observation that, with respect to the maximum RF-induced temperature elevations, inner tissues are significantly more affected by pulsed radiation at constant 6 minute averaged SAR than superficial tissues might be of biological interest, because heat perception mainly takes place inside the superficially located skin. However, it has to be noted that the time course of the exposure and the required peak RF power leading to such effects (a single high peak in repeated 6 minute intervals) are not typical for mobile communication devices.

Abstract

Directive 2004/40/EC sets action and exposure limit values for people working in electric and magnetic fields. Electric field action values for 50 Hz frequency might be exceeded in existing 400 kV air-insulated substations. Therefore measurements in Finnish 400 kV substations were conducted to find out whether the limit value of induced current density (10 mA/m^2) is exceeded in the human central nervous system. One of the most critical areas is the neck. Measurements were made with a specific system connected to the test person, who simulated practical work in actual and practical working conditions. The developed system measures the current induced in the head as well as the total current induced in the body of the test person.

The maximum average current density in the cross-sectional area of 40 cm collar-size neck was 6.81 mA/m^2 , even if the action value for the electric field strength was clearly exceeded. The margin to the limit value 10 mA/m^2 is obvious, but further analysis was necessary due to individual variations etc. Consequently, a model for analyzing current densities in the cross-sectional area of the neck, especially in central nervous system, was developed.

The model described 9 different tissues in the neck area. Currents and current densities in the tissues were calculated when the average current density had a given value. The result was that only 0.13 % of the total current in the neck area flows through the spinal cord causing in it a current density 0.72 mA/m^2 when the average current density in the neck area is 6.81 mA/m^2 (collar size 40 cm assumed). Thus, it seems that the substation workers are not exposed to current densities in practical work situations within the body, which would exceed the directive's limit value.

Keywords: *occupational exposure, induced current density, central nervous system*

1. Introduction

Power frequency electric and magnetic fields occur in electricity generation, transmission, distribution and consumption. Occupational exposure to electric fields is common especially in electricity transmission and distribution. Accordingly, exposure in certain places is larger than in other places. In 400 kV air-insulated outdoor substations the exposure of the workers to the electric fields is one of the largest areas. We will concentrate on electric fields instead of magnetic fields, because in 400 kV outdoor substations electric fields in practice cause more remarkable current density in the human body than magnetic fields.

The European Union (EU) sets action and limit values for occupational exposure to electric fields in directive 2004/40/EC. The action value for 50 Hz electric field is set as electric field strength and it is 10 kV/m . In case action value is exceeded the employer has to make sure the limit value will not be exceeded. Limit value is set as induced current density in the central nervous system in the head or trunk and it must not exceed 10 mA/m^2 . Limit value is set to protect tissues in the central nervous system for acute effects of exposure. [1]

MODEL FOR NECK WHEN ESTIMATING EXPOSURE TO ELECTRIC FIELDS AT 400 KV SUBSTATIONS

When estimating exposure to electric fields, the neck is a critical area, because current induced in the head flows through the neck into the trunk and the cross-section area in the neck is small compared with the trunk. Furthermore, the spinal cord as a part of the human central nervous system makes the neck an interesting area.

The Laboratory of Electrical Engineering and Health (LEEH) at Tampere University of Technology (TUT) has made several electric field measurements at Finnish 400 kV substations. At 75 % of the measured substations the action value 10 kV/m was exceeded already at the ground level. Higher values can be expected in maintenance situations, although live-line work tasks are not carried out in 400 kV level. Therefore further study of induced current densities was seen as necessary.

A study of induced current densities was done by using special measuring equipment which consists of a helmet coated with copper and having a transparent but conductive face shield, two commercial current recording ammeters, a commercial medical electrode and leads. The current induced in the helmet and shield was conducted away with a lead connected to the helmet. An ammeter was connected to the lead and the other end of the lead was connected to a medical electrode in test person's wrist. The test person wore insulated shoes and gloves and the medical electrode in the wrist was earthed with another insulated lead going along the body of the test person. Also the grounding lead had a recording ammeter. Hence, both the induced current in the helmet with face shield and in the whole body current could be measured. A schematic picture of the measuring arrangement is shown in Fig. 1.

Fig. 1 Schematic picture of the measuring arrangement [2]

The current induced in the helmet and shield is called helmet current I_{helmet} . Because the helmet is slightly larger than head, current induced in the helmet is larger than the induced current in the head in normal conditions. This error was compensated for by multiplying the helmet current by empirically defined correction coefficient k , which is 0.819.

LEEH made induced current measurements at 7 different 400 kV air-insulated substations. Altogether 125 measurements were made in 12 different work tasks. The tasks consisted of normal walking in the substation, climbing in the maintenance and inspection platforms as well as maintenance work from ladders or from persons being lifted. The largest value for induced helmet current was 105.8 μA . This current causes current density 6.81 mA/m^2 in the neck area when the neck cross-sectional area is assumed to be a circle with circumference 40 cm (typical collar size for men is 40 cm).

Current density 6.81 mA/m^2 gives an obvious margin to the limit value 10 mA/m^2 . However, individual variations in collar size may be rather considerable. Consequently, in order to get further analysis about 50 Hz currents and current densities in different tissues in the neck and especially in the central nervous system LEEH developed a model based on the cross-section of the neck.

2. Objectives and methods

2.1 Aim of the Study

The main aim of this study was to estimate with a developed model current densities in different tissues, especially in the spinal cord in the neck cross-sectional area. The purpose was to find current densities at 35 cm, 40 cm and 50 cm neck circumferences. Another aim of the study was to find out current percentages of induced head current in different tissues.

2.2 Description of the Model

The model is based on the anatomical picture of the cross-sectional area of neck. The anatomical picture was taken from source [3]. Each tissue in the anatomical picture was modeled by using circles, rings and half-rings as modeling shapes so that the shape fitted the anatomical picture of tissue as well as possible. The neck was also assumed to be a circular shape. A cross-sectional picture of the model is presented in Fig.2.

Fig. 2 Cross-sectional picture of the model

Tissue 5 includes arteries and veins, which are located on both sides of the model. Tissue 8 consists of five different nerves: spinal nerve, vagus nerve, phrenic nerve, sympathetic trunk and recurrent laryngeal nerve.

Windpipe (number 10) is assumed air with conductivity of 0 S/m. Muscle (number 1.) is a circle area, where tissues 2, 3, 4, 5, 8, 9, 10 create holes in.

Dimensions of the model are scaled when circumference of neck (collar size i.e. circumference of circle 7.) is changed. Dimensions of the tissues are presented in Table 1, when the diameter of the model is assumed d .

Table 1 Dimensions of the model, when the largest diameter is assumed as d .

MODEL FOR NECK WHEN ESTIMATING EXPOSURE TO ELECTRIC FIELDS AT 400 KV SUBSTATIONS

Tissue	Dimensions
1. Muscle	$0.901d$
2. Bone trabecular	$0.242d$
3. Spinal cord	$0.110d$
4. Thyroid gland	$0.396d$ $0.275d$
5. Blood	$0.055d$
6. Fat layer	$0.989d$
7. Skin	d
8. Nerves	constants
9. Gullet	$0.066d$
10. Windpipe	$0.099d$

Nerves are the only tissue in model, which have constant dimensions at all collar sizes. Diameters are for spinal and vagus nerves 0.20 cm, phrenic nerve and sympathetic trunk 0.10 cm and recurrent laryngeal nerve 0.05 cm.

Each tissue has its own conductivity value. Tissues with conductivity values are presented in Table 2.

Table 2. Tissues used in the model and their conductivities at 50 Hz. [4], [5]

Tissue	Conductivity (S/m)
1. Muscle	0.3500
2. Bone trabecular	0.0700
3. Spinal cord	0.0300
4. Thyroid gland	0.5200
5. Blood	0.7000
6. Fat layer	0.0400
7. Skin	0.1000
8. Nerves	0.0274
9. Gullet	0.5200
10. Windpipe (air)	0

2.3 Induced Currents and Current Densities

All the tissues in the model are connected in parallel. In a resistive model the conductance value G_i for the tissue i can be calculated by using equation (1), when conductivity value σ_i and total area A_i of the tissue i are known. Length of the neck is l (constant).

$$G_i = \sigma_i \frac{A_i}{l}, \text{ where } i = 1 \dots 9 \quad (1)$$

By using current distribution law in parallel connected circuit, currents I_i in tissues can be calculated by using equation (2).

$$I_i = k \cdot I_{helmet} \frac{G_i}{\sum_{i=1}^9 G_i}, \text{ where } i = 1 \dots 9 \quad (2)$$

Current percentages of head current p_i in tissue i can be calculated by using equations (1) and (2). Hence, we get final equation (3) for current percentages of head current.

$$p_i = \frac{\sigma_i A_i}{\sum_{i=1}^9 \sigma_i A_i} \cdot 100\%, \text{ where } i = 1 \dots 9 \quad (3)$$

Current densities J_i in tissue i can be calculated by using equation (4).

$$J_i = \frac{I_i}{A_i} = k \cdot I_{helmet} \frac{\sigma_i}{\sum_{i=1}^9 \sigma_i A_i} \quad (4)$$

3. Results

The model gives the current densities in various tissues in the neck area. Results were calculated with 35 cm, 40 cm and 50 cm collar sizes and maximum measured helmet current 105.8 μA by using equation (4). This helmet current corresponds to working in conditions where the local electrical field strength is highly non-uniform and clearly exceeds the action value limit. Induced current densities in each tissue are presented in Table 3. Average current densities in cross-sectional area of the neck are also presented.

The largest current densities in the neck area occur in blood (arteries and veins), thyroid gland, gullet and muscle. Current densities in bone, spinal cord, fat layer, skin and nerves stay below or near to 3 mA/m^2 even at 35 cm collar size.

Spinal cord is critical part in exposure because it is a part of the human central nervous system. According to the results current densities in central nervous system seem to stay below 1 mA/m^2 even at 35 cm collar size.

Table 3. Calculated current densities (mA/m^2) in different tissues at collar size 35 cm, 40 cm and 50 cm.

Tissue	Collar size		
	35 cm	40 cm	50 cm
1. Muscle	10.95	8.38	5.36
2. Bone trabecular	2.19	1.68	1.07
3. Spinal cord	0.94	0.72	0.46
4. Thyroid gland	16.27	12.45	7.97
5. Blood	21.90	16.76	10.72
6. Fat layer	1.25	0.96	0.61
7. Skin	3.13	2.39	1.53
8. Nerves	0.86	0.66	0.42
9. Gullet	16.27	12.45	7.97
Average current density in neck area	8.89	6.81	4.36

Current percentages in tissues were calculated by using equation (3). Results are presented in Table 4 at 40 cm collar size. Current distribution in tissues varies a bit depending on collar size. This results from nerves, which are not scaled as other tissues. However, the maximum variation is 0.1 % when varying collar size between 35 cm...50 cm.

Table 4. Current percentages in different tissues at collar size 40 cm.

MODEL FOR NECK WHEN ESTIMATING EXPOSURE TO ELECTRIC FIELDS AT 400 KV SUBSTATIONS

Tissue	Percent of head current (p_i)
1. Muscle	84.43
2. Bone trabecular	1.14
3. Spinal cord	0.13
4. Thyroid gland	7.41
5. Blood	2.97
6. Fat layer	2.34
7. Skin	0.77
8. Nerves	0.01
9. Gullet	0.80

According to results most of induced current flows through muscle. This is due to its conductivity and a large area in cross-sectional area.

4. Discussion

The model gives a more specific estimation about current distribution in the neck area. According to results current densities in the central nervous system stay clearly under limit value 10 mA/m^2 even if the collar size is small (35 cm). Hence, it seems that substation workers in practical outdoor work situations in 400 kV substations are not exposed to current densities that exceed the limit value of the directive 2004/40/EC.

According to the model the collar size for neck should be 16.5 cm in order to exceed the limit value. Such a narrow neck circumference is extremely rare, if not undiscovered in the working age population.

There are some simplifications in the model that cause errors in calculations. Modeling shapes differ from real tissue shapes and so they do not fit into tissues perfectly. This difference relates also to the circumference of the neck cross-sectional area, which is not exactly circular in the anatomical picture. Another principal difference from reality in the model is that cross-sectional area of neck is assumed the same in every position of neck length l . In reality the proportions of tissues varies depending on the position of cross-sectional area on neck.

One limitation of the model is that it is purely resistive and it does not take account mutual inductances, which occur between different parallel-connected tissues. However, impedances of biological material are mostly resistive below 100 Hz and contribution on capacitive component is of the order of 10 % in most cases [5]. Hence, the error caused by this limitation does not seem to be large.

When comparing current densities to a study by Dimbylow, P. [4], we can notice that current densities in the spinal cord are larger than in our study. Our neck model is suited to a ballpark estimation. A three-dimensional model based on for example MRI scan gives us a more accurate estimation.

For further analysis of induced current densities it may be necessary to develop cross-sectional practical models also for other areas in the human body. Such areas could for example be the chest or stomach, because the spinal cord as a part of central nervous system is part of both cross-sectional areas.

THERMODYNAMIC LAW AND THE PROBLEM OF STANDARDIZATION OF RADIOFREQUENCY ELECTROMAGNETIC RADIATION

YULIA CHUKOVA

e-mail: y.Chukova@mtu-net.ru

Abstract

The problem of radiofrequency radiation standardization is the most important problem of up-to-date-ness because all frequencies of radiofrequency radiation are used in different technical and domestic devices. The sharpness of this problem was elucidated half a century ago, when the USSR standard for microwave radiation was 1000-fold lower than the USA standard. In the USA and in many other countries, a power density of 10 mW/cm² has been adopted as a standard safety level, but in the USSR a value of 10 μW/cm² was adopted.

This problem exists both for microwave radiation and other radiofrequencies at the present time.

The thermodynamic theory of systems under electromagnetic radiation gives the general law of electromagnetic energy conversion into energy of chemical bonds (the Helmholtz free energy). This law gives the dependence of bioeffects on absorbed power. The thermodynamic law shows that there are two regions of bioeffects of radiofrequency radiation: thermal effects and isothermal ones (endergonic + exergonic effects). The USA standard is good only for thermal effects, but the USSR standard is valid for thermal and isothermal effects.

It is discussed a role of a good social decision for conservation of public health.

Introduction. The general principle of hygienic standardization

The general principle of hygienic standardization is simple. Hygienic research begins with the most great influences. In these conditions, there is a hundred-per-cent adverse effect (death, illness etc). Then the influence decreases and the adverse effect decreases too. At last a hygienist does not see an adverse effect. This point is called the no-observed-adverse-effect level (NOAEL) or no-observed-effect dose. This point is the final one of natural research. The following decision (standard) is the social act because all levels and doses below the NOAEL or no-observed-effect dose are determined as safe levels or doses (Fig.1). This statement was the general paradigm of safety in 20th century. This paradigm prevails today.

Fig.1

The principle of radiofrequency radiation standardisation in the 20th century

During the second part of the 20th century, there was considerable development and increase in the number of devices that emit nonionizing radiofrequency radiation. For example, microwaves (MW) were used in all sectors of our society for military, industrial, telecommunications, medical and consumer applications. This is the frequency range receiving the most attention in terms of biological interaction. This is due to the widespread use of high MW energy densities in highly populated areas. High energy densities of MW radiation cause heating of the human body. This is a dangerous effect and the principle of 20th century standardization for radiofrequency radiation was simple and common [1]. It has needed to determine the no-observed- heating-effect level. Safe conditions must be lower than the no-observed-heating-effect level. This statement was the general paradigm of safety in the 20th century for radiofrequency radiation and prevails today. In the USA, a power density of 10 mW/cm² has been adopted as the standard safety level [2]. Standards in different countries are different because shifts from the no-observed-heating-effect level are not equal.

For a long time there was only one exception to this rule: it was the Soviet standard on adverse microwave radiation effects. This standard was 1000-fold lower than the USA standard. Such a huge difference in the representation of an adverse effect was a result of the great experimental programme in the USSR in the middle of the 20th century.

In the USSR, standardization for microwave radiation was begun in 1956. Soviet hygienists studied at first the thermal effects of high-intensity radiation and then they took an interest in low-intensity radiofrequency radiation. They revealed that changes resulting from chronic or repeated exposure to low intensities of radiation are specific, initially reversible and affect the nervous system, myocardium, kidneys etc. About 70 photos of those changes are in an English book [3]. The reversible changes disappear after some time, if the exposure is ended. In other cases, the changes are permanent. The results of these researches were published both in Russian and in English [3, 4].

In the end, the Doctor-hygienist Z.V. Gordon (head of the laboratory of radiofrequency electromagnetic waves of the Institute of Labour Hygiene and Occupational Diseases of the Academy of Medical Science of the USSR) proposed for the Soviet microwave hygienic standard a power density of 10 µW/cm². Her suggestion

was supported by Admiral A.I.Berg, Deputy Defence Minister for the USSR. So, in the USSR the value of $10 \mu\text{W}/\text{cm}^2$ was adopted as the safety standard for microwave radiation. This led to the well-known difference of a factor of 1000 between the safety standards in the USSR and the USA. Thus, the Soviet standard was the most stringent standard in the world.

The Soviet standard has taken into account adverse non-thermal effects. It means that in the second part of the 20th century in Russia, the other independent paradigm of hygienic standardization of radiofrequency radiation has been adopted. This confusing picture was indeed the beginning of a hygienic discussion which has been long and unsuccessful. The situation can be changed by the thermodynamic theory of systems under electromagnetic radiation.

Thermodynamics is free from the terms “adverse effect”, “hazard” etc. These terms are known in medicine and biology. Thermodynamics deals with thermal and isothermal processes, the endergonic and exergonic ones, but every process can be useful or adverse from a view of life and from a human standpoint. The method of thermodynamics of irreversible processes in systems under electromagnetic radiation yielded interesting results for up-to-date hygiene and physiology. One result is related to the radiofrequency safety problem.

Resume of advances in the nonequilibrium thermodynamics of isothermal processes in systems under electromagnetic radiation

Thermodynamics deals with the energy of processes and the efficiency of energy conversion. It began with a study of technical systems under electromagnetic radiation (luminescent lamps and solar cells). The considered system is given in Fig.2, with the definitions. In this system, there are three kinds of energy conversion: radiation into radiation, radiation into Helmholtz free energy and radiation into heat.

The basic theoretical work was done by L. Landau in 1946 [5]. At that time, he was not yet a Nobel prize winner. Landau has estimated the first way – luminescence. The result for luminescence, which has been obtained by L. Landau, has struck scientists very much. Only some scientists can believe that optical cooling is possible. Optical heating is habituated for us. But during the 1970s the thermodynamically predicted result was obtained in many systems under laser light; and in 1997 the Royal Swedish Academy of Sciences decided to award the Nobel Prize in Physics jointly to Steven Chu (USA), Claude Cohen-Tannoudji (France) and William D. Phillips (USA) for the development of methods of cooling atoms with laser light.

It is foreseeable that in the future a device will be designed which combines the characteristics of a radiation-source and a refrigerator. Thermodynamics does not forbid a such device.

The second way is interesting for solar cells and bioeffects of electromagnetic radiation. For the second way of energy conversion, thermodynamics did not give any wonderful result [6], but the solar cell presented a possibility of direct numerical verification of the thermodynamic theory through a correlation with experimental data. This comparison became possible because theoretical physicists have gone from the thermodynamic limit efficiency estimation to the real efficiency calculation for processes with losses. The numerical correlation of experimental data with the theory was not only satisfactory, but the fit of theory and experiment was also quite good. Furthermore, the thermodynamic method may work even for living systems. It allowed understanding and explanation of many experimental results in living systems, which had not previously been exhaustively explained [7,8].

Symbols and Notations:

T - temperature

• time derivative sign

Energy

Corresponding entropy flux

U_r - internal energy of reactants

\dot{S}_r

U_p - internal energy of products

\dot{S}_p

\dot{W}_a - absorbed power

\dot{S}_a

\dot{W}_l - power of luminescence

\dot{S}_l

\dot{Q} - thermal flux

\dot{Q}/T

\dot{S}_i - entropy generation rate in system

F - Helmholtz free energy

$$F = U - TS$$

(1)

η - real efficiency

$$\eta = (F_p - F_r)/W_a = \Delta F/W_a$$

(2)

$\Delta F > 0$ endoergonic process

$\Delta F < 0$ exoergonic process

For bioeffects of electromagnetic radiation, there is a need to examine conversion of energy of electromagnetic radiation into energy of chemical bonds, i.e. into Helmholtz free energy. The efficiency of this conversion is given by formula (2). On the basis of the first and second equations of thermodynamics, for the steady state of a system, the efficiency η of MM radiation conversion at constant temperature is given by:

$$\eta = 1 - T (\dot{S}_a + \dot{S}_i) / \dot{W}_a \quad (3)$$

From formula (3) it is obvious that the efficiency η is determined by two entropy terms. The first entropy term \dot{S}_a (entropy flux of absorbed power) is dictated by the absorbed power characteristics and is defined by formula (4):

$$\dot{S}_a = 2\pi k c^{-2} \int v^2 (1 + \ln \rho) dv \quad (4)$$

where c is the velocity of light, k is the Boltzmann constant, v is a frequency and

$$\rho = c^2 E_v / 2\pi h v^3 \quad (5)$$

E_v is the spectral density of absorbed power \dot{W}_a

$$\dot{W}_a = \int E_v dv \quad (6)$$

The second entropy term \dot{S}_i (entropy generation rate) is determined as

$$\dot{S}_i = \alpha \dot{W}_a + \beta \dot{W}_a^n \quad (7)$$

where α , β and $n \neq 1$ are constants connected with the system characteristics.

According to formulas (3 – 7), the dependence of efficiency on absorbed power \dot{W}_a (or spectral density of absorbed power E_v) is given by the left-hand curve of Fig.3

Fig.3 demonstrates two simple and important results:

- 1) A system at constant temperature can show three types of behaviour in response to energy absorption. In order increasing absorbed power, they are:
 - exergonic isothermal processes
 - endergonic isothermal processes
 - endergonic nonthermal processes
- 2) Endergonic processes have a beginning and an end.

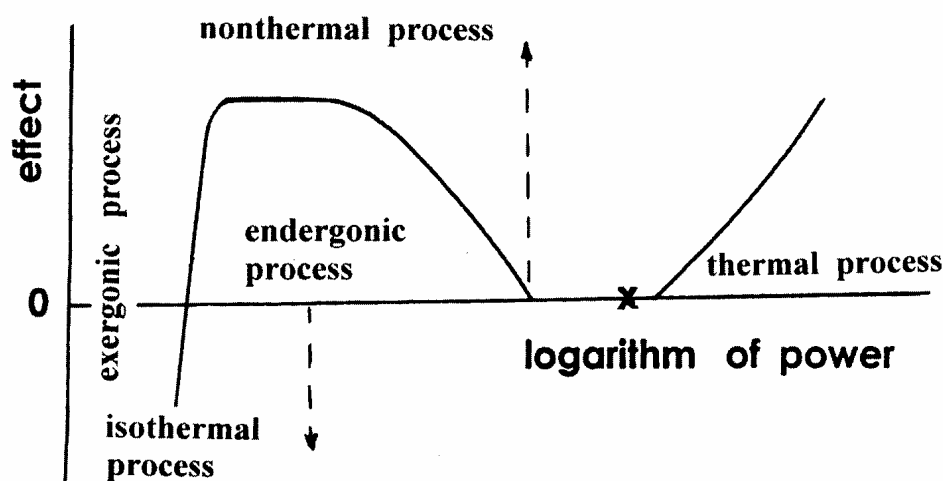

Fig.3

The rapid rise and the plateau of the left-hand curve of Fig.3 are determined by the entropy of absorbed power according to (4), but the position of the curve on the logarithm of absorbed power axis (the point of its intersection with the absorbed power axis, where the real endergonic processes are balanced out by exergonic processes) is dictated by the linear term of the entropy generation rate according to (7). The falling region of the left-hand curve is defined by the nonlinear term in the entropy generation rate. This is the second term in formula (7) for the condition $n > 1$.

A qualitative agreement between the thermodynamic theory of endergonic processes and experimental data was demonstrated in a series papers [9–12] and in two books [7, 8]. That is why this aspect of the problem will be omitted in the present paper.

So, endergonic processes have a beginning and an end at some level of absorbed power, but an experimentalist can study the system not only at constant temperature, but also at increasing temperature for high absorbed power. According to thermodynamic theory in this case, we have two results: a system with no biological effects; and thermal processes in a system (right-hand curve in Fig.3).

Thermal effects of radiofrequency radiation have been studied for almost one hundred years and for thermal processes there is sufficient scientific clarity. That is why this aspect of the problem is omitted in the present paper. The interval without biological effects is poorly understood and it is therefore useful to recall a paper by scientists at the University of Utah (Salt Lake City, USA), who studied this interval [13]. They exposed monolayer cell cultures (for example BHK-21/C13 cells) to high levels of microwave radiation without significant microwave-induced heating ($\leq 0.1^\circ\text{C}$). They showed that for the frequency interval 38-48 GHz at a power density of 292 mW/cm^2 and for 65-75 GHz at a power density of 177 mW/cm^2 bioeffects of microwaves were absent [13].

Thermodynamic conclusions for hygienic standardization

The curves of Fig.3 are very important for the hygienic standardization of radiofrequency radiation. They show that the 20th paradigm of hygienic standardization takes into account only thermal processes in living systems under electromagnetic radiation. In the light of thermodynamic theory, it is clear that the experimentalists finished their research when they reached the interval between thermal and nonthermal effects. All current hygienic standards, except the Russian standards, lie in this interval (cross).

The standards of different countries are different because they are not equally close to the no-observed-heating level (the starting point for thermal processes). But they are all interposed between thermal effects and nonthermal endergonic ones.

From thermodynamics it is obvious that current international standards relate to thermal processes only.

The Soviet hygienic standard for radiofrequencies holds both for thermal and for isothermal processes. That is why it is 1000-fold more severe than the USA standard and all other standards.

It is obvious that in the future national and international standards will be changed. They will become more severe and, in the long run, isothermal effects will taken into account. Then the science of hygiene will have a theoretical basis as a third point of support, in parallel with the experimental and social ones. This is demonstrated schematically in Fig.4. But hygienists do not at present know the theoretical basis and the situation is therefore not simple.

Fig.4

Radiofrequency hygiene of the transitional period

The main current international documents, “Directive 2004/40/EC of the European Parliament and the Council of 29 April 2004 on the minimum health and safety requirements regarding the exposure of workers to the risk arising from physical agents” and “ICNIRP Guidelines for limiting exposure to time-varying electric, magnetic, and electromagnetic fields (up to 300 GHz)”, take into account only thermal processes under radiofrequency radiation. How should hygienists deal with real situations today? There are two ways. One way is very simple: it is to wait for laboratory isothermal experiments to show scientifically what the standard of absorbed power must be. In this case, hygienists will leave the people without protection for a long time. But there is another way: a social resolution of the problem, i.e. a precautionary approach. Social decisions may vary, which means that national standardizations will be original, as is now indeed the case. Some examples are given below.

Poland

Polish hygienists understand that limits based on ICNIRP are not too liberal in the case of chronic occupational exposure, and the regulations established in Poland contain limits on permissible exposure which are more restrictive than the EC Directive and the ICNIRP Guidelines. The Polish standardization system allows harmonisation with the EC Directive/ICNIRP basic restrictions and, at the same time, the practical application of a precautionary approach in the occupational environment.

In Poland, there are three levels of exposure [14]:

- high-level and dangerous zone,
- medium-level and safety zone,
- low-level for outside the safety zone.

For pregnant women and young workers (below 18 years), the levels of restricted occupational exposure in Polish Standards (2002) are 2-3 times lower than international regulations. For thresholds of permissible environmental exposure, they are 10 times lower.

Sweden

It has long known that the Swedish occupational standards for personal computers are more severe than international ones.

Austria

The strictest precautionary approach has been established in Austria. It is the so-called “Salzburg Model” [15,16]. The “Salzburg Model” was created in the city of Salzburg in 1997- 1998, when the Department of Public Health of the Federal State of Salzburg was requested by the Salzburg Provincial Parliament, the director of the Department of Health and several mayors to provide a medical evaluation of the GSM fields emitted from mobile telecommunications base stations. The aim of the Salzburg Model is the implementation of a precautionary strategy for the protection of public health against electromagnetic fields.

The so-called “Salzburg precautionary value” is equal to 1 mW/m^2 (or $0.1\text{ }\mu\text{W/cm}^2$) for the bands of 900 MHz – 1800 MHz. This frequency band is used by GSM base stations. It is useful to compare the “Salzburg precautionary value” with the ICNIRP (1998) standard of $4 - 10\text{ W/m}^2$, which is based on thermal effects in the same frequency range. The difference is 4 orders of magnitude. This difference accords well with theoretical estimates of the difference between the thresholds for thermal and isothermal processes.

Austrian hygienists understand that the Salzburg precautionary value is based on biological effects of low-intensity exposure (isothermal effects).

The decision of the Salzburg authority is a wise decision, and is in accordance with the WHO policy [23]. One can compare this decision with Napoleon’s decision. As is known, Napoleon Bonaparte created a domestic code. According to Napoleon’s code, the father of a child born in wedlock is the husband. In real situations, if the father is unknown, the husband is considered as the father. This decision is dictated by expediency, rather than truth. Napoleon’s decision has been a wise decision, because it has saved the law-courts and the population from unnecessary trouble. Napoleon’s decision has become a principle of legislation in many European countries for two centuries. Today, this problem is solved by scientific methods because science can establish paternity with high accuracy.

The “Salzburg Model” offers some advantages over Napoleon’s decision, because the “Salzburg Model” corresponds to thermodynamic predictions. Thermodynamic law supports the Salzburg precautionary level.

It is now apparent that this work will be the subject of experimental investigation, as attested by the Austrian-Spanish paper [17].

Summary

Thermodynamic theory shows that there are two independent regions of biological effects of radiofrequency radiation: thermal and isothermal ones. Thermal effects are very simple, well studied and standardized. Isothermal effects are complicated to study and their standardisation is for the future.

The precedents of the Salzburg model and the Soviet (Russian) standard are the first steps in a new hygienic science and a new system of standardisation, which will be able to protect public health against adverse effects of radiation. These are real attempts to execute the WHO plans and intentions.

Acknowledgement

I wish to thank Prof. O.P. Gandhi (University of Utah, Salt Lake City, USA), who made available a complete set of his papers on this subject.

I thank the research workers of the University of Utah for a very difficult experiment, which is very important for thermodynamics and hygiene.

Abstract

This presentation will summarize the results of several human volunteer studies carried out at Swinburne University over the last 7 years. The outcomes (significant unless otherwise stated) were:

- Tests of cognition (n = 120 subjects; battery of 8 tests): When adjusted for co-variables, worse performance in simple reaction time and choice reaction time; worse performance in some measures of information retrieval, but improved speed of processing of information held in memory.
- Event Related Potential pilot study (n = 12 subjects; auditory stimuli): Reduced N1 amplitude and latency to non-target and increased P3 latency to oddball target stimuli; worse reaction time performance.
- Event Related Potential main study (n = 120 subjects; auditory, visual and cognitive task stimuli): no significant changes in ERP-related parameters.
- Sleep study (n = 50; polysomnography): REM latency reduced by 16%. EEG alpha power enhanced by 8% during 1st non-REM period.
- Overnight melatonin (metabolite) output (n = 55): Overall no change, but 27% reduction in normalized output pre-bedtime.

These results will be compared for overall internal consistency and with studies from other laboratories. Part of the program of the Australian Centre for Radiofrequency Bioeffects Research is to extend some of the studies.

Introduction

The basic question our research program has sought to answer is: do the emissions from mobile phone handsets lead to an immediate change in a person's neuropsychological performance, such as ability to react to stimuli, recall information, perform tasks accurately, get a good night's sleep and so on? The specific hypotheses we formulated were on the basis of research available to us in the planning phase. An extensive literature review was taken at this time (Hamblin & Wood 2002). This identified EEG alpha power increase in response to radiofrequency (RF) exposure as being the most consistent observation

Methods

Exposure to RF was accomplished by the use of a popular handset, programmed into GSM pulsed mode (0.25 W average) using the manufacturer's software, giving a constant output over the time of the experiment, typically 1 – 2 hours. The output was checked in three ways: i) with dipole antenna; ii) direct connection to RF power meter and iii) by measurements in SAR phantom. The maximum 10g-averaged SAR value obtained was 0.11 W/kg (Hamblin et al 2006), with the phone attached to a cradle placing the handset in a normal position next to cheek. A number of checks were made: firstly, that the participants could not detect audible cues from the handset circuitry; secondly that ELF pickup in EEG electrode leads was not significant (Wood et al 2003) and thirdly that the SAR value was not affected by the presence of EEG lead wiring. In the case of auditory stimuli, an additional test ensured that the test tones (which were delivered by air-tube ear inserts) were uncontaminated by EMI from the phone handset.

A number of biological endpoints were assessed as follows: a) speed & accuracy in performing (mainly paper & pencil) cognitive tasks; b) Event-related potentials (ERPs): specific changes in EEG evoked by visual, auditory & cognitive stimuli; c) sleep architecture: quality and type of sleep following 30 min of phone exposure just prior to going to bed and d) the output of urinary melatonin metabolite: before and after sleep in both exposure conditions.

The basic procedure followed was of two types: for the cognition & ERP experiments, there were two testing sessions 1 week apart each with one of two exposure conditions: a random number generator determined which of exposure condition A (sham) or B (actual exposure) occurred first. To minimise practice effects alternate forms of the cognitive tests were given: the tests in each battery were given in random order (but in the same order between the two exposure conditions). The test were given twice at each session (4 times altogether), one before and once during the (real or sham) exposure. The outcomes were scored as a difference between performance before and performance during exposure, then score for weeks A & B were compared.

For the sleep study the procedure was somewhat different: participants stayed overnight for the Saturday and Sunday nights of two successive weekends. The Saturday nights were for adaptation to sleeping in the laboratory and on the Sunday nights the A or B type exposure was given for a period of 30 minutes prior to getting into bed. The monitoring electrodes were not attached until the exposure had finished. Polysomnography was carried out until 6 am the next morning. Urine was collected before getting into bed and at 6 am: urine volumes, creatinine and 6-hydroxy-melatonin sulphate (aMT6s) concentrations were measured.

In statistical analysis of results the potential confounding of multiple comparisons was recognised. Where possible we used prior hypotheses based on literature expectations: in these confirmatory hypotheses $p < 0.05$ was taken as the critical value for changes being regarded as significant. In hypothesis-generating comparisons, the critical p value was taken as 0.05 divided by an effective number of independent comparisons. For example, where the EEG was typically measured from 62 scalp sites: data from several sites were grouped and trends across the scalp studied (giving just 2 levels of laterality and 3 levels in the front/back direction).

Outcomes

1. *Effects on Cognition* (Keetley et al 2006)

In this study of 120 volunteers, a battery of 8 tasks were given, but task scores yield 18 measures of cognitive performance. The results were adjusted for co-variables: sex, age & educational level where there was literature evidence for this. It was found that participants scored worse in reaction time & information retrieval tests, but showed improvement in speed of processing of information held in memory. We concluded that basic memory tasks were impaired, but higher cortical functions improved

2(a). *ERP pilot study* (Hamblin et al 2004)

This was a small hypothesis-generating study of 12 volunteers. An auditory 'oddball' task was studied: responses to the 'oddball target' stimulus (t) and 'non-target' stimuli (nt) were considered separately. For the 'nt' responses, N1 amplitude was reduced (50%) and latency was 8.7% less with exposure. For 't' responses, P3 latency was 8% longer. Reaction Time (RT) was 10% worse.

2(b). *ERP main study* (Hamblin et al 2006)

This followed on from the above and was a study of 120 volunteers. For the auditory and visual 'oddball' tasks: 't' and 'nt' responses were considered separately. ERP amplitudes and latencies at specific sites were analysed, along with RT to 't' responses in both the auditory and visual tasks. No significant changes were found in relation to these parameters. Future analysis will concentrate on ERP changes from various scalp regions derived from factor analyses together with Event Related-Desynchronisation/Synchronisation (ERD/ERS) and Choice

Reaction Time (CRT) recorded during a cognitive task, which was a card-sorting task which was also conducted as part of the test battery. Psychological activation, as well as investigation into all above parameters by age, gender, previous mobile phone use, hemisphere exposed and laterality is also currently being undertaken.

3. Sleep study stages (Loughran et al 2005)

This was of a group of 55 volunteers (5 who had to be excluded because a sleep disorder was revealed during the subsequent sleep analysis). Ten standard sleep parameters were compared for RF effect: all were non-significant, except for rapid eye-movement (REM) sleep latency, which was reduced 16% by exposure (and which was a serendipitous finding). The EEG Alpha band power (range 11.5 – 12.25 Hz) was shown to be significantly enhanced (by 8%) in the 1st non-REM period (and this supported a prior hypothesis).

4. Sleep study melatonin (Wood et al 2006)

The urine melatonin metabolite (aMT6s) was measured in pre-and post bed-time samples in the same 55 volunteers involved in study 3. Overall, there was no change in total output (pre- + post-bedtime: 14.1 vs 14.6 µg). When values were normalised to urine creatinine concentration (which is considered to give a more precise estimate of aMT6s output), there was a significant reduction (by 27%) in pre-bedtime samples (Sham: 7.7; Exposed 5.6; units: ng aMT6s/mg creatinine). However, the distribution showed that 4 of the subjects were outlying the normal distribution (all in the same direction). If these were eliminated from the analysis the difference was not significant.

Summary

The results of these separate studies are currently being evaluated for internal consistency and for consistency with results from other laboratories. Under the program of the Australian Centre for Radiofrequency Bio-effects Research some of these studies are being replicated using some of the same cohort of subjects and using 3-G type exposures.

Grant Support

This research was supported by grants 78/3718 (Stough & Wood) and 154905 (Wood & Stough) from the National Health and Medical Research Council of Australia.

ABSTRACT

The effect of magnetic field (MF) exposure on microvascular blood flow is controversial with no clear evidence of any one effect. In this study, we investigated the effect of a complex, low frequency, electromagnetic pulse (CNP) on microvascular blood flow when stimulated with acetylcholine (vasodilator). The effect of CNP exposure on blood flow (after 30 and 60 min) when stimulated by 3 concentrations of acetylcholine (Ach) was tested in the peripheral muscle microvasculature of a rat and measured using laser Doppler flowimetry. A mixed design ANOVA indicated that there was a main effect of time, and a main effect of Ach concentration (positive control). There was no significant interaction between time and exposure type due to the large variance created by the Ach concentration; however, a power analysis projection of the data suggests that with additional rats a significant effect would be present at the 0.1 mM Ach concentration. This data will further be analyzed using spectrographs to identify possible imprints of the CNP in the blood flow recordings, as well as any other frequency differences that are present between the sham- and CNP-exposed animals. In light of the present results, it would appear that the CNP modestly increases microvascular blood perfusion after 60 min of exposure in the rats that received 0.1 mM Ach compared to sham-exposed animals. These findings are important in that one potential 'side-effect' of MF exposure to this particular MF sequence has been investigated.

MICROCIRCULATION AND CNP

INTRODUCTION

The effect of magnetic field (MF) exposure on microvascular blood flow is controversial with no clear evidence of any one effect. Published literature is mixed, however, it could be suggested that results are mostly divided into 2 categories¹: those studies that suggest that MFs lead to an increase in perfusion, and those studies that support a biphasic effect of MFs. The former group of studies indicates that when blood vessels are resting at a normal tone, MF exposure leads to an increase in perfusion (both during and after exposure)^{2,3}; while the latter studies indicate that when vessel tone is either low or high, MF exposure alters vasomotion so that normal vessel tone is re-established⁴. The observed variation in published studies is likely attributed to the variation in tested parameters (duration of exposure, time-varying vs. static MF, localization of exposure, MF strength) and species (mice, rats, humans).

In this study, we investigated the effect of a specific pulsed MF sequence, a complex neuroelectromagnetic pulse (CNP), on microvascular blood flow when stimulated with a vasodilator (acetylcholine). The CNP has been shown by our lab to be effective in providing analgesia⁵ for snails, mice, and humans, therefore we were interested in its potential effects on other biological systems, such as the microcirculatory system.

Numerous applications and benefits could be derived from locally manipulating microcirculatory blood flow. For instance, the ability to locally modify blood flow may be of benefit to wound healing, site-specific absorption of drugs, and re-perfusion of ischemic tissue. Conversely, if an individual was receiving MF therapy for a particular condition unrelated to blood flow, understanding other effects of that MF (e.g. microcirculatory effects) would be of importance.

According to previous research, results from this study should be explained by 1 of 2 theories: A.) The CNP will provide a homeostatic effect. That is, when acetylcholine (Ach) is administered, blood flow should increase, however, the CNP will cause resistance against this blood flow increase and no effect or a reduced effect on perfusion should be observed. B.) In agreement with our preliminary data⁶ and other research showing that MFs increase perfusion, the CNP will in some way enhance the effects of Ach on blood flow leading to an increase in perfusion. It is proposed that nitric oxide may be involved in the potential interaction of Ach with the CNP.

OBJECTIVE

The objective of this experiment was to determine the effect of CNP exposure (after 30 and 60 min) on blood flow when stimulated by Ach in the peripheral muscle microvasculature of a rat.

METHOD

100 male Sprague-Dawley rats (210-290 g) were housed on a 12hr/12hr light/dark cycle and were provided with food and water *ad libitum*. All procedures were performed in accordance with the *Ethics Review Board* at the *University of Western Ontario*.

Rats were anesthetized using pentobarbital sodium (65mg/kg of mass) and surgery was performed on the left hind limb. The extensor digitorum longus (EDL) muscle was carefully exposed and allowed to stabilize for half an hour prior to the MF exposure. Individual rats were then placed within the set of Helmholtz-like coils and a laser Doppler flow meter probe was lowered directly on top of the EDL. Specifics of the coils and MF are as follows: 1.2 m diameter for the coil that generates the vertical low frequency (< 1000 Hz) MF with a 200 μ T peak (400 mT/s). The sequence consists of 5 pulse segments (each 853 ms) with an average frequency of 72 Hz separated by an increasingly long refractory period (110-1200 ms).

A Time 0 (prior to MF exposure) measurement was taken for 8 min using PeriMed for Windows software. The MF (CNP) was then turned on. After 30 min had elapsed from the end of the Time 0 recording, a second measurement was taken (Time 30) for 8 min. After 60 min had elapsed from the end of

the Time 0 recording, a final (Time 60) measurement was made again for 8 min. For each recording, the same procedure was followed: 20 sec of un-stimulated blood flow was recorded to obtain a baseline and then Ach was dropped directly on top of the EDL. Three different concentrations of Ach were used: 0.1, 1, and 10 mM. Prior to each Ach injection, phosphate-buffered saline was injected on the EDL as a control measure.

At the end of the experiment, rats were euthanized via an intra-cardiac injection of pentobarbital. The Time 30 and Time 60 peak blood flow values were normalized to the Time 0 peak values and the results were analyzed using SPSS 12.0.

RESULTS

A mixed design analysis of variance was performed to test the effects of CNP exposure on blood flow, using time as a repeated measure. There was a significant difference in peak blood flow response across the 3 tested time points ($F(2, 179) = 18.15, p < 0.001$). The Time 60 values were lower than the Time 30 values. Also, as expected, there was a significant interaction between injection type (0.1, 1, or 10 mM Ach), our positive control, and time of exposure ($F(4, 184) = 3.92, p < 0.05$). There was no significant interaction between time and exposure type due to the large variance created by the Ach concentration; however, a power analysis projection of the data suggests that with additional rats a significant effect would be present at the 0.1 mM Ach concentration. Please refer to Figure 1 for the normalized peak blood flow response to Ach over time. Note that the greatest effect of the CNP appears to be occurring at the lowest concentration of Ach (0.1 mM). This is illustrated in Figure 2.

CONCLUSION

In light of the present results, it would appear that theory B – ‘CNP increases microvascular blood perfusion’ could possibly explain the obtained data. After 60 min of CNP exposure, the rats that received 0.1 mM Ach showed a modest increase (12 %) in peak blood flow response compared to sham-exposed animals. Analysis of a greater sample size is required to confirm this finding; however, these results are in support of preliminary data collected from our lab⁶.

These findings are important in that one potential ‘side-effect’ of MF exposure to this particular MF sequence has been investigated. It would appear that MF exposure of this type modestly increases blood flow in the microvasculature after 60 min of exposure.

SUMMARY

The objective of this experiment was to determine the effect of 30 and 60 min exposure to a specific pulsed electromagnetic field (CNP) in the peripheral muscle microvasculature of a rat. Changes in blood flow, when stimulated by 3 different concentrations of acetylcholine (a vasodilator), were recorded using laser Doppler flowimetry. After 60 min of CNP exposure, the rats that received 0.1 mM acetylcholine (the lowest concentration) showed a modest increase (12 %) in peak blood flow response compared to sham-exposed animals. Analysis of a greater sample size is required to confirm this finding. These findings are important in that one potential ‘side-effect’ of MF exposure to this particular MF sequence has been investigated.

ABSENCE OF LINEAR CORRELATION BETWEEN BIOLOGICAL EFFECTS AND POWER DENSITY IN THE NON-THERMAL RF RADIATION RANGE

SIANETTE KWEE

DEPARTMENT OF MEDICAL BIOCHEMISTRY, UNIVERSITY OF AARHUS,
BUILDING 170,
DK-8000 AARHUS C, DENMARK.

Abstract

During the past years many studies, including our own, have shown significant changes in various cellular processes caused by rates of adsorption at very low level of RF irradiated tissue.

In our investigations we found that MW-EMF exposure of cells down to SAR 0.0002 - 0.002 W/kg caused changes in the cell cycle, which could explain the resulting changes in cell proliferation. Therefore it can be assumed that the observed changes were due to non-thermal RF effects. This could also be concluded from our experiments at various temperatures, which showed that changes in cell proliferation were significantly higher in RF exposed cells than in non-exposed cells at the same temperature.

Nevertheless present safety levels are still based on thermal effects only.

Another argument in favour of non-thermal effects are the so-called "window" effects, i.e. only at specific power densities and/or frequencies, significant effects are seen. These "window" effects have only been observed in the non-thermal range. The same applies to the phenomenon of adaptation.

In this study it will be shown that, though changes in cell proliferation following RF exposure varied with the different SAR levels, they were not linearly proportional with increasing SAR levels, but exhibiting so-called "window" effects.

Effects also varied with the length of exposure time and after 24 h of exposure no changes in cell growth were detected any more. Moreover repeated exposure did not show any difference from results found at a single exposure. This can only be explained by adaptation of cell growth to RF exposure.

So a maximum increase in cell proliferation was only found at certain power densities and exposure times. This can be considered to be characteristic for non-thermal effects.

Introduction

This study is part of our on-going work to find a mechanism for the biological effects of electromagnetic fields (EMF), in particular non-thermal effects.

From laboratory, clinical and epidemiological studies various effects have been reported after exposure to microwave electromagnetic fields. In course of time many theories have been proposed for these effects. On the other hand, very few experimental studies have appeared that offer an explanation for the reported effects. At first it was assumed that biological effects of radiofrequency (RF) or microwave (MW) fields are solely the result of heat generation. Unfortunately the misconception still persists that all effects of MW-EMF are thermal. Even though we have started to talk about non-thermal effects of MW fields, they are being discussed in terms traditionally applied to heat effects. This is also reflected in the official standard levels for safe exposure that are only based on heating and are based on average, whole-body irradiation of laboratory animals. However, a lot of tissue damage has been done long before a laboratory animal shows behaviour changes or dies from thermal effects.

At present we have enough experimental evidence to question the validity of standards based only on thermal effects. In particular fundamental research on cell tissue cultures has presented the strongest evidence. During the past years many studies, including our own, have shown significant changes in various cellular processes caused by rates of adsorption at very low

level of RF irradiated tissue. At these levels it was also observed that the biological effects were not always linearly proportional with higher power densities or exposure times, but there were so-called "window effects". It also appeared that these window effects are characteristic for non-thermal effects.

We have chosen cell proliferation as the parameter to follow the changes in mammalian cell tissue cultures after exposure to EMF. Our experiments were all done at very low field strength, so the observed changes could be considered as non-thermal effects of EMF.

Methods

Materials, cell cultures, EMF - MW exposure, experimental protocol and calculations have been described before [1-4].

Results and discussion

ELF magnetic fields

In previous work [3] we showed that in case of ELF-EMF exposure there was a linear correlation between field strength and the exposure time to obtain a maximum effect as shown in Fig. 1. However it can be seen that this proportionality is not present within a certain power range. As shown in Table 1 there is a plateau at 40-50 μT or a so-called "window".

Figure 1: ELF electromagnetic fields: Dependence of maximum change in proliferation rate on exposure time and field strength.

MW magnetic fields

The cell cultures were exposed to 960 MHz microwave fields at various power levels and exposure times.

As shown in Table 2 and 3 this resulted in a significant change in cell growth, dependent on energy level and exposure time. Repeated periods of exposure did not seem to change the effects.

It is notable that increased energy levels are not proportional to an increased change in cell growth. At certain levels there is a negative change, while others show a positive change. Also linearity between exposure time and change in cell growth is different and dependent on energy levels. At varying energy levels the maximum change is seen at 20 or 30 or 40 min (Table 4).

At specific levels there is an increase and at others a decrease in growth change at longer exposure times. The latter could indicate adaptation. So adaptation is apparently also dependent on energy level, since at certain levels adaptation takes place already at shorter exposure times than at other levels.

S.KWEE

In conclusion it can be said that the same linear correlation between power level, exposure time and growth change was not as clear in the case of RF exposure as it is for ELF exposure. As observed also by others the effects registered are not linear over the whole radiofrequency field density spectrum. This can be related to the oscillatory nature of cell growth. Apparently the interaction of microwave radiation with cellular oscillators contributes more to these effects than in case of ELF electromagnetic fields.

Summary

We have studied the effects of ELF and RF exposure on cell growth in cell tissue cultures. Our experiments were done at very low field strength and in case of RF fields corresponding to a SAR not exceeding 2.1 mW.kg^{-1} . So the changes observed can be considered as non-thermal effects.

In case of exposure to ELF we can see one specific window at a field strength of 40-50 μT .

In case of RF exposure the picture is more complicated: there are several windows or rather maxima and minima dependant not only on field strength, but also on exposure times. This is certainly due to the different nature of RF radiation and also the modulating frequencies. It has been shown that at constant frequencies the biological effects are much less or even absent.

Longer exposure times and recording periods will result in adaptation and this might be the reason why under different experimental conditions no changes were observed. Due to the process of adaptation it may often no longer be possible to measure changes in cell proliferation when repeated exposures or and much longer exposure times are applied. It is known that under these conditions increasing Hsp concentrations are required to produce the effects as described above. So the Hsp mechanism is certainly also responsible for the resulting adaptation.

It is clear that these window and adaptation effects are crucial for long-term health effects of RF radiation [5] at non-thermal level.

In the thermal range these effects cannot be observed [6]. This is another reason to reconsider the present safety standard, which only applies to thermal effects of RF radiation.

Acknowledgements

The complete exposure system, including the SAR calculations, were designed and assembled by the late prof. Povel Raskmark.

Abstract

A magnetic field exposure metering system has been developed to be utilized in indoor MV/LV substation measurements. The metering system follows the guidelines published by the International Commission on Non-Ionizing Radiation Protection (ICNIRP) and the EU directive of 2004 for public and occupational exposure. It can be used to measure magnetic field values, total harmonic distortion of the magnetic field, magnetic field exposure ratios for public and workers, load current values and total harmonic distortion of the load current. This paper presents the developed magnetic field exposure metering system, quantities to be measured by the system and exemplary measurements.

1. Introduction

Measurements of electric and magnetic fields in living and working environment have increased because the public concern on the fields has increased. Due to their possible health effects, the International Commission on Non-Ionizing Radiation Protection (ICNIRP) has published guidelines, in which upper limits for public and occupational exposures have been presented /1/. Based on these guidelines, European Parliament and Council have adapted a Directive on minimum health and safety requirements regarding the exposure of workers to electromagnetic fields in 2004 /2/. The European Parliament and Council Directive has to be nationally implemented in 2008. In Finland and in several other EU countries the legislation for occupational exposure to low frequency electric and magnetic fields is still missing. In addition to that common practices and standards have to be created for everyday measurements and estimation of magnetic field exposures.

Table 1 presents occupational exposure reference levels of the ICNIRP guidelines and the Directive. The limit for allowed public exposure to 50 Hz magnetic fields is 100 μ T and for occupational exposure 500 μ T.

Table 1. Public /1/ and occupational /1, 2/ magnetic field exposure reference values.

Frequency, f (Hz)	Public allowed magnetic flux density, B (μ T)	Occupational allowed magnetic flux density, B (μ T)
Up to 1	4×10^4	2×10^5
1-8	$4 f^{-2} \times 10^4$	$2 f^{-2} \times 10^5$
8-800	$5 f^{-1} \times 10^3$	$25 f^{-1} \times 10^3$
800-820	6.25	$25 f^{-1} \times 10^3$
$(0.82-65) \times 10^3$	6.25	30.7
$(0.065-0.15) \times 10^6$	6.25	$2 f^{-1} \times 10^6$
$(0.15-10) \times 10^6$	$0.92 f^{-1} \times 10^6$	$2 f^{-1} \times 10^6$
$(10-400) \times 10^6$	0.092	0.2
$(0.4-2) \times 10^9$	$4.6 f^{0.5} \times 10^{-6}$	$10 f^{0.5} \times 10^{-6}$
$(2-300) \times 10^9$	0.2	0.45

In 2003 ICNIRP expanded their guidelines by taking into account the harmonic components of the magnetic field with phase angles /3/. This statement provides accurate guidelines, in practice, to estimate the magnetic

field exposure due to harmonic components, but it has not been referenced widely. In the case of electricity transmission and distribution only frequencies from 50 Hz to 65 kHz contribute to magnetic field exposure. So far, there is only one commercial magnetic field exposure meter, which is able to consider this frequency range including the phases of the magnetic field components. Measurement method utilized in that meter seems to stand up to a close examination. However, the output of the results in this commercial meter is inadequate for advanced measurements.

Electromagnetic fields have been studied at the Tampere University of Technology (TUT) since the 1980's. In recent years, the research has concentrated on evaluating exposure to magnetic fields. Previously, measurement system at TUT was based on commercial magnetic field meters and power quality analyzers /4/. In that system, the exposure was calculated afterwards enabling advanced magnetic field exposure measurements considering the phases of the harmonic components. However, load current of the indoor MV/LV substation and magnetic field were measured with different equipments, thus not exactly simultaneous. There was a clear need for an improved measurement system providing directly simultaneous measurements of all physical quantities of interest. In this paper we will describe a magnetic field exposure metering system utilized in indoor MV/LV substation measurements meeting these requirements.

2. Measurement methods

In addition to magnetic field exposure measurements, the system measures synchronously load currents. The measurement system saves magnetic field values, total harmonic distortion of the magnetic field, magnetic field exposure ratios for public and workers, load current values and total harmonic distortion of the load current.

A conservative estimate of the cumulative magnetic field K' normalized to the measured 50 Hz magnetic field value B_1 is calculated according to the ICNIRP guidelines /1/ by

$$K' = 1 + \sum_{k=2}^{16} k \frac{B_k}{B_1} + \sum_{k=17}^{1300} 16 \frac{B_k}{B_1}, \quad (1)$$

where k is the index of harmonic frequency and B_k is the measured magnetic field of the harmonic component k /5/. According to the ICNIRP guidelines the magnetic field exposure ratio R' is

$$R' = \frac{B_1}{B_{L,1}} K', \quad (2)$$

where $B_{L,1}$ is the 50 Hz magnetic field reference level. The allowed upper limit for the magnetic field exposure ratio R' is 1. The method presented in equations 1 and 2 has been shown to overestimate the exposure ratio close to 50% in indoor distribution substation by /4/.

According to the ICNIRP statement /1/ and the anticipated implementation of the EU Directive /2/ the maximum cumulative magnetic field K normalized to the 50 Hz magnetic field component B_1 can be obtained as the maximum value of the sum of harmonic components inside a cycle time of 20 ms as follows

$$K = \left\{ 1 + \sum_{k=2}^{16} k \frac{B_k}{B_1} \cos(k\omega_1\tau + \varphi_k + \phi_k) + \sum_{k=17}^{1300} 16 \frac{B_k}{B_1} \cos(k\omega_1\tau + \varphi_k + \phi_k) \right\}_{\max}, \quad (3)$$

where ω_1 is $2\pi f_1$, φ_k is the phase angle of B_k , ϕ_k is the biological correction angle at frequency $k \times f_1$, f_1 is fundamental frequency of 50 Hz. Further, the magnetic field exposure ratio R is

$$R = \frac{B_1}{B_{L,1}} K. \quad (4)$$

The calculation procedure of equations 3 and 4 was presented by /6/ and also by /3/ and /7/. The calculation procedure of the magnetic field exposure ratio based on equations 3 and 4 was earlier used to study the validity of the method based on equations 1 and 2 in indoor distribution substation environment by /4/.

The maximum cumulative magnetic field K of equation 3 can be presented in a more general form as a function of time t for long term measurements as follows

$$K(t) = \left\{ \sum_{f=8\text{Hz}}^{800\text{Hz}} \frac{f}{f_1} \frac{B_f(t)}{B_1(t)} \cos[\omega\tau + \varphi_f(t) + \phi_f] + \sum_{f>800\text{Hz}}^{150\text{kHz}} 16 \frac{B_f(t)}{B_1(t)} \cos[\omega\tau + \varphi_f(t) + \phi_f] \right\}_{\max}. \quad (5)$$

This approach, in principle, is a continuous integration of the magnetic field spectrum corresponding closely to the weighted peak approach /3, 6/. In the weighted peak approach the waveform is weighted with a simple high-pass filter with a 3 dB cut-off frequency at 800 Hz. This approach has been used in the measurements of this paper. However, one must note that a discrete summation of equation 3 is quite adequate for power engineering applications and takes into account all essential frequencies.

3. Meters

In the measurements a 3-axial EnviroMentor BMM-3000 magnetic field meter (accuracy $\pm 5\%$, RMS) was used. Measured signal was further processed and stored with data acquisition system NI-DAQPad-6015 by National Instruments. Measurement program is named as Keikko6 and created with LabView 7.1. Fig. 1 presents an exemplary screen from a magnetic field measurement.

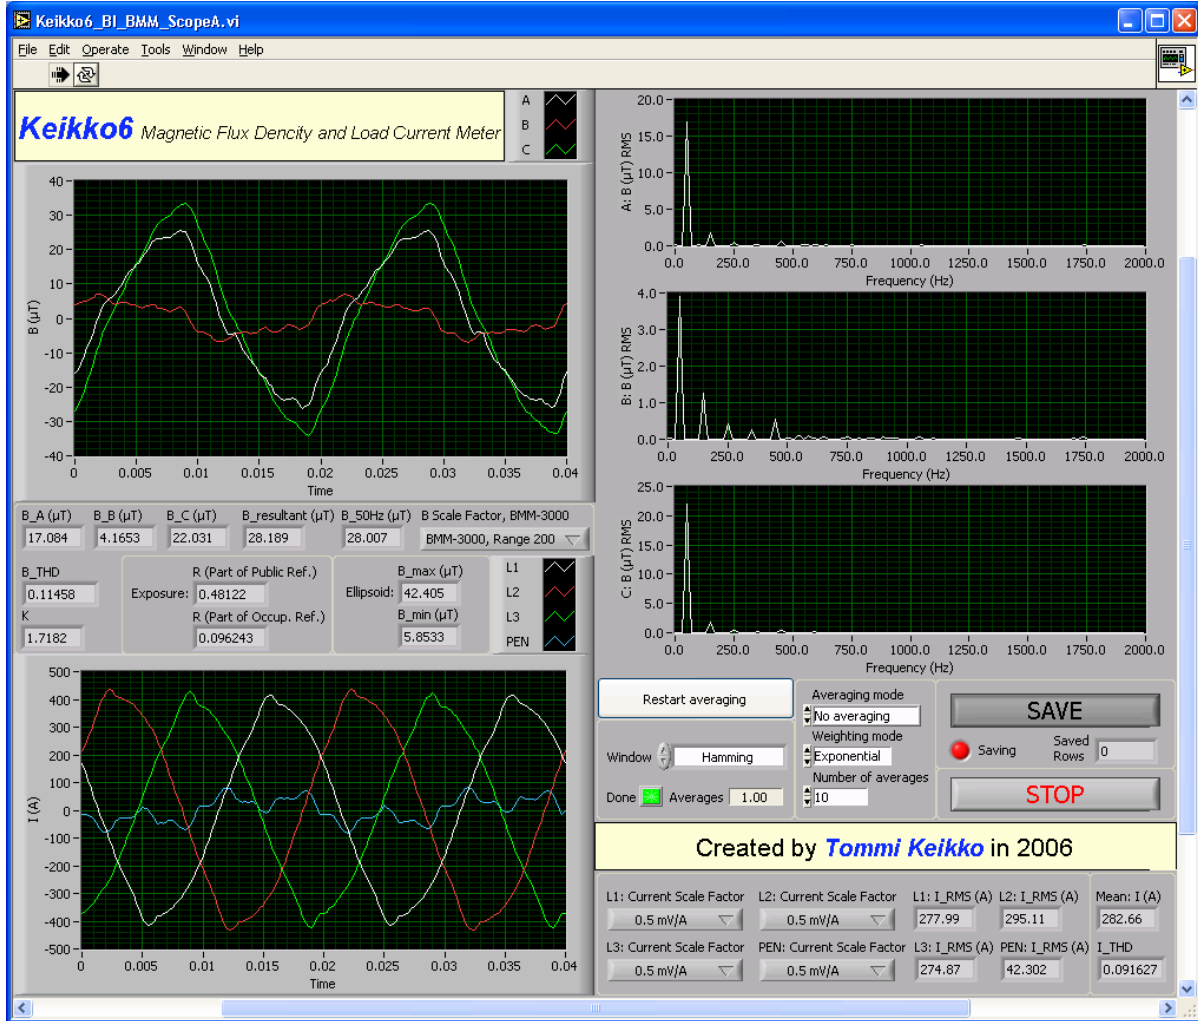

Figure 1. Output screen of the magnetic flux density and load current meter with exemplary measurement results.

The developed metering system saves magnetic field values, total harmonic distortion (THD) of the magnetic field, magnetic field exposure ratios for public and workers, load current values and total harmonic distortion of the load current. Magnetic field values B_A , B_B , and B_C in Fig. 1 are RMS components of the orthogonal magnetic flux density values B_x , B_y , and B_z . Also their resultant value and the resultant 50 Hz value are shown. Total harmonic distortion of the magnetic field B_{THD} is calculated, as follows

$$B_{THD} = \sqrt{\frac{\sum_{k=2}^{1300} \sum_{D=x,y,z} B_{k,D}^2}{\sum_{D=x,y,z} B_{1,D}^2}}, \quad (6)$$

where D is the index of the orthogonal magnetic field component. Further, the cumulative magnetic field K normalized to 50 Hz, and public and occupational magnetic field exposures are saved as well.

In addition, elliptic polarization of the magnetic flux density is measured. Ellipsoid based on maximum and minimum magnetic field values during five 50 Hz cycles presents the polarization grade of the vibration.

Load current values I_{RMS} are RMS values for the three phase currents I_{L1} , I_{L2} and I_{L3} and the combined protective earth and neutral conductor current I_{PEN} . Mean current is the average value of the three phase currents.

Mean total harmonic distortion of the load current $I_{THD,Mean}$ (I_{THD} in Fig. 1) is determined and calculated from the load currents of the phases, as follows

$$I_{THD,Mean} = \sqrt{\frac{1}{3} \sum_{L=L1,L2,L3} \frac{\sum_{k=2}^n I_{k,L}^2}{I_{1,L}^2}}, \quad (7)$$

where L is the index of phases.

4. Measurement set-up

Magnetic field and load current measurements were performed inside 12 indoor MV/LV substations. Fig. 2 presents a photo of an indoor distribution substation, its surroundings and the measurement set-up in one typical substation structure having the LV connection near the ceiling. The magnetic field measurement point nearby the LV connections was determined by considering public exposure in the residence above an indoor distribution substation. The structure of the substation and the building was examined before each measurement.

Figure 2. Measurement set-up in a typical indoor distribution substation having the LV connection near the ceiling. Dimension a is the thickness of the ceiling and dimension b is the distance between the LV connection and the ceiling. /4/

In cases, where the LV connection was not close to the ceiling, the magnetic field sensor was located in the ceiling of the substation above the LV connection or above the expected highest magnetic field source, if possible. Fig. 3 presents a typical measurement set-up, where the LV connection goes on the floor level. Low voltage switchgear can be seen in left-hand photo.

Figure 3. Photos of a measurement set-up in an indoor MV/LV distribution substation, where LV connection is located on the floor level.

Right-hand photo presents the MV/LV transformer. Meters and other measurement equipment are on the floor of the substation. What comes to the public exposure on magnetic fields in the residence above the substation, the space above the transformer is the interesting area to be measured. This area is rounded in the right-hand photo in Fig. 3 and is considered in this paper.

5. Measured magnetic field waveform exposures

Different types of indoor distribution substation structures were selected for measurements to obtain an overall picture on the public magnetic field exposure. Measurements were carried out during the spring 2006. Loads were apartment houses, office buildings or school buildings. The loads of the distribution substations were mostly heat loads, fluorescent and tungsten lamps, computers, and other electronic devices. These loads cause harmonics in the load current that increase the total magnetic field in the substation and decrease the allowed reference value of the 50 Hz magnetic field component. Measured locations and periods are presented in Table 2, where I_{max} is the highest 15 minutes average load current during the previous year and I_{Rated} is the rated load current.

Table 2. Measured indoor distribution substations in spring 2006.

Substation	Transformer		LV connection structure	Measurement period (h:min)
	I_{max} (A)	I_{Rated} (A)		
A	1000	1155	Cables near ceiling	21:35
B	1100	1155	Cables in floor	18:28
C	350	722	Cables near ceiling [†]	Period 1: 69:57 Period 2: 28:55 [§]
D	650	1443	Bus bars near ceiling	22:19
E	560	722	Cables near ceiling	18:08
F	730	722	Cables near ceiling	117:11

[†] special structure: two \times tree phase cables

[§] measured in two periods and two locations, period 1 near LV switchgear and period 2 near transformer

Magnetic fields were measured during 1 to 5 day periods. Transformers in substations B, F and K were near their capacity limits. The other substations were clearly within the capacity of their transformers. More detailed results are presented for substation A to describe the advantages of our metering system. Long periods can be measured to consider varying load situations when metering exposure to magnetic field. Due to data handling purposes long measurements can be saved automatically to several files. We used a measurement interval of 1 s and saved 30 000 measurements in one output file i.e. a measurement of 8 hours and 20 minutes. In the following we present a set of measurements done during the first metering lot for substation A to demonstrate our metering systems. This substation has the same type of structure as in Fig. 2.

Fig. 4 presents 50 Hz magnetic field component and public exposure ratio during the first metering lot for substation A. The public exposure ratio correlates, on the average, well with the fundamental magnetic field component, which is in accordance with small variations of $K(t)$ as a function of time being close to 2 (Fig. 5). Thus, according to equation 4, the public exposure ratio has to be multiplied by a factor of 50 μ T to obtain the 50 Hz magnetic field component in Fig. 4. This simply means, that the total magnetic field exposure including the harmonic components is, in practice, two times the exposure due to the fundament frequency.

Figure 4. Measured 50 Hz magnetic field component and the public exposure ratio in substation A.

Candidates to explain varying $K(t)$ are the total harmonic value for the magnetic field and the relative load current defined as load current divided by the rated current of the transformer (1155 A for substation A), which are presented in Fig. 5. There seems to be a slight negative correlation between the cumulative magnetic field normalized to 50 Hz and the relative load current in agreement with earlier observations [4]. The same negative correlation exists also between B_{THD} and the relative load current. A strong positive correlation is seen between $K(t)$ and B_{THD} , as expected.

Figure 5. Measured $K(t)$, B_{THD} and relative load current as a function of time for substation A.

Based on Fig. 5 the correlation between $K(t)$ and B_{THD} is clear. The shapes of the curves seem to be almost similar having only minor differences. Further, based on [4] load current and magnetic field harmonics had correlation. The same was tested for substation A in Fig. 6. Correlation between the load current and the magnetic field total harmonic distortions is clear also in these measurements.

Figure 6. Load current and magnetic field harmonics for substation A.

The coefficient between I_{THD} and B_{THD} is close to 3 in this measurement. This coefficient is the same than in [4], although the determination of the total harmonic distortion values differs. Previously the values were determined based on the highest load current and highest magnetic field component. The more advanced determinations in this paper were presented in equations 6 and 7.

Summary of the results for all measurement periods is presented in Table 3, where I_{load} is the highest load current, B_{period} is the highest magnetic field and R_{period} is the highest magnetic field public exposure ratio during the measurement period. Significance of the measurement result is determined based on congruence between the measured location and the possible public exposure so that ** means a significant result and * means a indicative result. R_{max} is the highest magnetic field public exposure ratio during the measurement period scaled to the rated load current.

Table 3. Key results for the measurement periods.

Substation	Significance	I_{load} (A)	B_{period} (μ T)	R_{period} (%)	R_{max} (%)
A	**	633	32.7	0.73	1.33
B	*	851	120.8	1.57	2.13
C	**	Period 1: 326	Period 1: 7.90	Period 1: 0.17	Period 1: 0.37
	*	Period 2: 279	Period 2: 41.6	Period 2: 0.90	Period 2: 2.32
D	**	688	44.3	0.71	1.49
E	**	349	26.7	1.37	2.83
F	**	478	51.4	0.82	1.24
G	*	378	7.40	0.27	0.51
H	**	454	75.4	1.37	2.18
I	**	352	13.1	0.20	0.42
J	*	343	27.5	0.41	0.86
K	**	567	12.1	0.33	0.67
L	**	445	75.6	1.73	2.81

Significance is valuated based on the structure of the indoor MV/LV substation. For bus bars or cables near the ceiling the location of the magnetic field sensor corresponds to the floor of the space above the substation. If the sensor is located in the ceiling of the substation, the results of the measurement periods are indicative. In the Table 3 the public exposure ratio during the measurement period exceeded value one in 3 out of 9 significant measurement periods. When the exposure ratio is scaled with the rated load current the value one is exceeded in 6 out of 9 significant measurement periods. The exposure ratios exceeded one in 1 and 2 out of 4 indicative measurement periods, respectively.

6. Summary

Magnetic field exposures are presented considering harmonics for the case of 12 indoor MV/LV distribution substations. Based on the measurements, the public exposure often exceeded the reference value in rooms above indoor distribution substations. Further, this means that indoor distribution substations can cause public exposure. Another relevant question is do the structures of the present indoor MV/LV distribution substations produce too high magnetic fields considering the EU Directive /2/, which will be nationally implemented within the EU by 2008.

In this paper, magnetic fields were measured with a new and advance metering system. All important magnetic field and load current values were measured with a simultaneous measurement. This new metering system gave relevant results and made further analyses possible. Previous measurements and references supported results and analysis made with the new metering system. Furthermore, magnetic fields can cause disturbances in measurement or control systems and in electrical devices, and that is another possible use of this new metering system.

Based on the measurements of substation A, the load current is the primary cause for the magnetic field level. Fig. 7 presents the measured magnetic field generation defined as magnetic field divided by the load current for substation A.

Figure 7. Measured magnetic field generation in substation A.

A generally accepted basic approximation is that the magnetic field is considered to be directly proportional to the load current. This seems to be roughly true for substation A. The average value for the magnetic field generation in Fig. 7 is around $5 \mu\text{T}/100 \text{ A}$. However, it varies most of the time between 4 and $6 \mu\text{T}/100 \text{ A}$. Because the curve in Fig. 7 is not linear, the phase angle differences of the currents have important role when estimating magnetic fields.

The structural differences between indoor distribution substations will have a significant impact on magnetic fields. Therefore, to create general magnetic field exposure estimates, a wider range of grouped structures of the indoor MV/LV distribution substations and with grouped load parameters should be analyzed.

ALGORITHM FOR NOISE-DATA REDUCTION FOR LONG-TERM EMF MONITORING SYSTEMS

H. HAIDER¹, A. NÖHRER¹, G. NEUBAUER¹

¹ARC SEIBERSDORF RESEARCH GmbH, A-2444 SEIBERSDORF, AUSTRIA
HARALD.HAIDER@ARCS.AC.A T

Abstract

In addition to present popular ‘in situ’ EMF-measurements performed at critical locations like schools, hospitals or in front of base stations for one-time, long-term evaluations of RF-fields become more and more essential. This is especially because of the continuously increasing number of new applied technologies and even more emitting base stations. To perform such long-term investigation, fully automatic, stand alone EMF-monitoring stations are suited very well. Typically, several of such stations are connected to one environmental network, fully remote controlled by one server. To yield maximum of information, each station is continuously in operation, performing frequency selective measurements and generating an enormous amount of measurement data. The data communication often represents the bottleneck of such systems and therefore the reduction of these data becomes very essential. By implementing an intelligent algorithm for data reduction directly on the measurement station this problem could be reduced. Therefore we will provide in this paper a methodology suited for a considerable reduction of noise points without losing any relevant signal information. The specific nature of this algorithm and his efficiency in data reduction will be discussed and explained, including how it works and what parameters are needed. The results which can be achieved with this technique are demonstrated with the existing monitoring system ‘Field Nose’ from ARC Seibersdorf research.

I. Introduction

Today more than 1 billion people are using mobile telephones world-wide, about 360 million people of them in Europe. Such wide use of this technology led to an increase in the environmental exposures to RF-fields and the introduction of new, additional technologies has intensified this process.

In the meantime most countries have national laws, regulations, guidelines or standards and more or less accurate defined measurement procedures and protocols how to handle RF-exposure. The ICNIRP guidelines [1] are used as reference in most European countries. However, many countries apply more restrictive limits, e.g. Switzerland and Italy [2]. Independent of the absolute values of limits, different measurement procedures are used in different countries. In general, the limit are frequency dependent and given over a wide frequency range. There are different concepts regarding the kind of exposed people and the considered areas, i.e. general public versus workers or controlled versus uncontrolled areas. For EMF-exposure evaluation, the contributions of all relevant RF-emitters for the whole body have to be investigated, considering individual signal form, frequency range, bandwidth, polarisation, direction and deviation over time. This leads to a lot of essential requirements for EMF measurement systems and especially also for the data evaluation procedures of such equipment. Another need for adequate measurement and evaluation techniques is the demand for epidemiological studies on the potential health effects caused by the numerous RF-emitters. In the frame of an international project the feasibility of epidemiological studies on potential health effects arising due to the exposure from mobile telephone base stations was jointly assessed by a team of RF experts and epidemiologists. A major outcome of this study was the need for reliable exposure assessment procedures [3]. Frequency selective, monitoring exposure assessment equipment is one of the best suited approaches to assess exposure in a reliable way. Also one COST 281 program activities are focusing at that topic.

II. EMF Measurement Systems

One of the most important requirements for EMF-measurement systems for exposure evaluation is an isotropic (receiving) radiation characteristic over the whole frequency range to add all contributes of different RF-emitters (technologies) in the same way, independent of their distance and direction in relation to the measurement point

and their polarisation. Further the sensitivity of the measurement systems have to be high enough to measure very small signals of modern communication technologies of a few mV/m as well as the dynamic range has to be large enough to consider signals close to the limit level, which is typical at 4 V/m to 60 V/m. Of course measurements have to consider the effective field strength or power flux density independent on the kind of signal or technology (e.g. modulation, pulsing or frequency hopping) and they should be fast, easy to handle, accurate and reliable. The instruments should be small, low cost, easily to operate and the requirement to enable long-term evaluation is essential for RF-dosimetry. Currently three different technical solutions are on the market to perform EMF measurements and each one has its individual assets and drawbacks in relation to the requirements mentioned above.

First there are the well known wideband field probes. They are low priced, easy to handle, have a wide frequency range typically from 100 kHz to 3 GHz, good isotropic characteristic and they are popular also for other kind of measurements e.g. for classical EMC. Some types also enable to select some frequency dependent limits and return the result in percentage of that limit. Unfortunately this is a global result without any information of the relative contribution of the considered transmitters. Also the sensitivity is limited at about 0.1 V/m. Therefore field probes are popular and well suited for preliminary measurements, e.g. to decide if and at what position frequency selective measurements should be performed.

A second group is represented by so called transmitter-selective or narrowband instruments. With these instruments, which are relatively new on the market, fixed or user definable frequency bands corresponding with the bands of transmitter-technologies are measured. Each narrowband is evaluated separately but of course there is, similar to field probes, no possibility to get any information about signal intensity within a band e.g. any differences in channels or for competitive providers. Depending on the system, data acquisition in the time domain is very flexible, from milliseconds to minutes for long-term evaluations. Typically 7 to 15 narrow-bands are measured together at each time cycle and therefore the resulting data amount is relatively easy to handle. Some systems are small enough to carry them on the body or in a rucksack and use these instruments for 'live time' RF-dosimetry during the whole day or to evaluate typical exposure at a working place. Typical limitations of those systems are given if signals occur out of the predefined narrow-bands because they were totally ignored. Another problem is caused by crosstalk of bands close together which is often used for up- and downlink of one technology, but could also affect different technologies, if their frequency bands are proximate to each other. Increasing the number of RF-technologies or even the number of bands which should be evaluated will increase that crosstalk problematic. The sensitivity of the systems is typically given at the data-sheets with 10 to 50 mV/m, which is suitable for most applications. Unfortunately the isotropic behaviour and measurement uncertainty are often not clearly specified especially if these data are needed for the individual bands.

The third group of systems is a more or less traditional method using a wideband antenna or field sensor in combination with a frequency selective measurement instrument like a spectrum analyser. Due to the fact that no antenna has an isotropic radiation characteristic by itself, one solution consists in the addition of the contributions of three measurements of an antenna with a dipole like radiation pattern to yield an isotropic receiving characteristics for the system. ARC Seibersdorf research developed small RF-antennas with a dipole like radiation pattern and established the so-called 'Add3D Method' [2] in 2002. An automatic positioner can be used to realize the three orthogonal antenna orientations. Figure 2 is showing a schematic drawing of the ARC Seibersdorf research system 'Field Nose Complete' and a picture of the real system (see also at <http://www.seibersdorf-rf.com>). This EMF-measuring and monitoring system is fully remote controlled by the software 'Nose', and enables the user to perform automatic measurements as well as many data evaluation procedures. The following examples and evaluations of that publication are based on this system.

Other manufacturers offer systems based on three small sensors with dipole characteristic and switch between them or combine them by an electrical network. In those cases there is the challenge to get an acceptable isotropic radiation pattern of the system because the three sensors interfere with each other. On the other hand such systems are faster, because they need no time to rotate the receiving antenna.

All these systems based on frequency selective spectrum analyser measurements enable individual RBW-settings, rms-, peak- or average signal detection, max-hold trace functionality, very high dynamic range and best sensitivity (low noise level) caused by the performance of state of the art spectrum analysers. The measurement time for a frequency scan is different and mainly depending on the trace speed, the analyser settings, the number

Figure 2: EMF-monitoring system Field Nose Complete (schema and picture)

of repetitions and the sensor type. Measurement cycles of a scan from e.g. 80 MHz to 2.5 GHz can be done within a minute or less. With these frequency selective measurements most information is generated and available for evaluation on the one hand. On the other hand especially that large amount of data can make problems. One possible way of the challenging task to reduce the amount of data without any loss of relevant information is presented in the next chapters.

III. Evaluation problematic of frequency selective systems

Figure 3 is showing a measurement trace and the corresponding data evaluation of a frequency selective, wideband EMF-measurement performed in the centre Vienna. Radio and TV signals as well as the typical downlink signals of mobile phone technologies (GSM 900, DCS 1800 and UMTS) can be seen. The frequency bands of those technologies are marked by coloured, vertical areas corresponding to technology bands as common for band-selective data evaluation. The measurement was done from 80 MHz up to 2.5 GHz using a Field Nose system with a PCD8250 antenna, a 5 m long RF-cable and an Anritsu MS 2711D spectrum analyser.

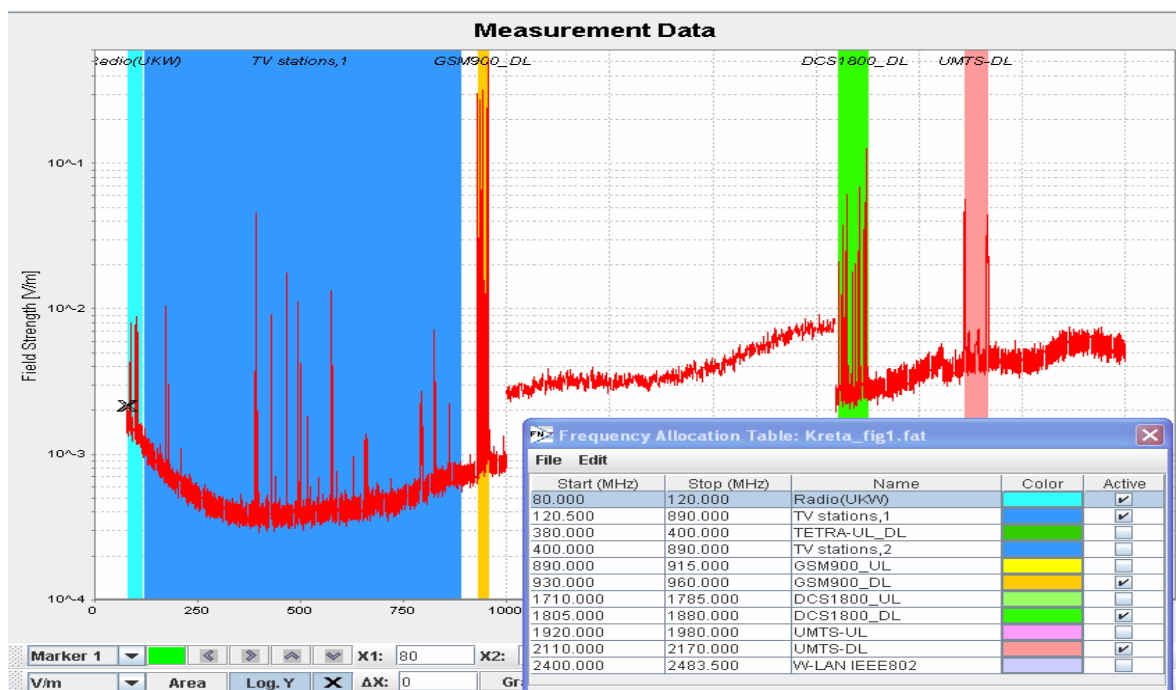

Figure 3: Frequency selective EMF-wideband measurement trace (overview measurement) from Vienna

The characteristic ‘bathtub’ noise floor for this frequency selective, wideband measurement trace can be seen very clearly because of the logarithmic scaling of the field strength axis. It is caused by the noise floor of the spectrum analyser itself (primary depending on its RBW setting, internal attenuator setting or an activated preamplifier), the cable- and connector losses and the antenna factor of the used PCD-antenna. Also caused by the logarithmic scaling and the high sensitivity of the system, the small signals from radio and TV-stations and less strong mobile technology signals with a few mV/m can be detected well. For the measurements from 80 MHz to 1 GHz and from 1.8 GHz to 2.5 GHz a RBW-setting of 100 kHz was used to get a good frequency resolution of the measured technologies. Between those bands we do not expect any signals. Therefore the RBW at that frequency range was set to 1 MHz to save time for the frequency scans and to reduce the number of measurement points too. The higher noise floor does not disturb in that case because of the lack of public communication technologies in that range.

Caused by the selected RBW-settings with 100 kHz respectively 1 MHz and the wide frequency range, 17.000 measurement points are needed for the one single scan according to Figure 3. For example if one scan should be performed each 5 minutes during one day, 288 scans respectively nearby 5 million measurement points are needed. To save that data including measurement information like settings, used antenna and cable factors, time and date, the Field Nose system needs approximately 15 MByte of memory, if the data was stored in a binary format. Even up-to-date computers need considerable time (from a few seconds to minutes) to process such big amount of data, e.g. to print them on screen, perform any data calculations, load and save them or to send them to a host system computer in case of a monitoring system consisting of several measurement stations. In practice measurement may differ to that example, but still a huge amount of data could be produced and the resulting time delay for data processing will not be accepted by the user. This would limit the application of frequency selective systems for long-term evaluation in a considerable way.

IV. Algorithm for noise-data reduction

Having a look to Figure 3, it can be seen that most of the measurement points are representing noise. The only important information of this noise floor is that all signals below that level could not be detected by the measurement system and not considered for any evaluation. On the other hand if the level of noise is deep enough, the signals below that do not affect the evaluation results in a significant way. This fact is the starting point to overcome the problem of extremely large amount of data for frequency selective measurements. Based on an effective signal detection method it should be possible to divide the signals from noise sequences and reduce or eliminate the noise data. Of course the efficiency of that process depends on the relation of signal and noise parts in a measurement scan but especially for wideband measurements it should reduce the number of data points in a considerable way and help to speed up the systems.

The simplest solution segmenting noise and signals is a user defined threshold line near above the noise. All values above that threshold will be accepted as signals. Unfortunately this works only for small frequency ranges because for wideband measurements the noise floor usually is frequency dependent and there is the question where to set the threshold limit. Another method is to select the largest signals by a peak detection algorithm. There of course is always the question of a proper predefinition of the number of relevant peaks as well as the problem that the highest signals not necessary are the one with most of energy because of different bandwidths. Approaches like they are typical in the noise reduction of sound signals were not applicable because of the fact that EMF signals sometimes look like noise to them. Other approaches which are used in image processing are not really applicable too.

Therefore we developed a specific algorithm for signal detection considering the unique requirements in the area of EMF signal processing. The processing of the data can be applied to measured data that is already available, but the main intention was to perform the reduction during measurements on the embedded system of the Field Nose Complete system. Therefore the reduction algorithm works completely automatically but it is also possible to set some parameters manually to improve the results for certain measurements. The noise data can be reduced so that the noise floor is still present or it is possible to remove the noise data completely. Signals are not affected by the algorithm in any way.

The noise data reduction algorithm itself works in the way that first the noise floor is detected and segmented from the signals. The next step is to calculate the new reduced noise floor with less data points and finally this new noise floor is merged with the original signal data. The most difficult part was to find a way how to distinguish very efficient between the noise floor and the signals because sometimes signals share many characteristics with the noise. For that purpose an upper and a lower envelope of the noise are calculated by

using a 'Noise Height' factor in dB. Based on this predefined noise-amplitude factor the decision is derived if the measured points are noise or not. If a Gaussian distribution function is assumed for the noise, this factor should be 2 sigma of the noise amplitude to catch approximately 99 % of noise by the envelope curves. For that process it is essential to consider not only the difference between adjacent measurement points, but also the amplitude differences of proximate points have to be considered.

Between the envelope curves of the noise a new noise curve is calculated with much less points in correlation to the original measured curve. The reduction of noise points for the calculated noise curve is predefined in the software or can be selected manually by a percentage value, which is typically around 90 % (this is an input value for the software and not correlating with exact 90 % of noise point reduction; see also Table 1). The resulting, data reduced measurement curve consists of the original signals matched with the sequences of reduced noise points. In Figure 4 an example of the signals is displayed. The thick (red) curve is the new calculated curve with reduced number of points in the noise sequences and unchanged points for all signals.

Figure 4: Noise points reduced measurement trace with noise envelopes

However there are still some kinds of signals making problems like typical UMTS signals. Because of their 5 MHz bandwidth and the RBW-setting of 100 kHz these signals look like noise to the algorithm. This can be solved in a second signal check, where it is assumed that the noise floor is continuous. Jumps in the noise floor because of different analyser settings are handled by the evaluation of each measurement trace separately.

The next step to reduce the amount of data is to eliminate the noise sequences totally. Therefore simply all noise points are neglected and only the signals are still part of the data reduced, noise points excluding trace. In the graphic chart the flanks of signals are connected by a line. In Figure 5 the UMTS-DL band of the overview measurement from Vienna (Figure 3) is shown magnified. For the original measurement trace the noise data reduced trace and the trace with eliminated noise points were calculated and displayed together. The difference in the number of needed data points for these three signals is obvious.

Another powerful effect of the presented algorithm besides the data reduction is the possibility to evaluate the effective signal power without any incorrect additional integration of noise to the signals. To demonstrate that we have again a look at the UMTS band of Figure 5 respectively Figure 6 at left side. This time the vertical bands in Figure 6 are representing the DL-channels of the Austrian UMTS providers, which are used for data evaluation of the three UMTS-traces. On the right side of this figure the evaluation results are given. In all 3 diagrams the results for the active channels are identical because the algorithm does not affect the signal parts.

Figure 5: UMTS-DL traces after noise data reduction

Also the results of the other channels, representing the noise power, are very similar for the original trace and the noise data reduced trace. However for the trace without any noise points the evaluation result for inactive bands is zero. Therefore the presented algorithm enables the user to add only the power of measured signals to yield in fact EMF-field strength evaluation results without any disturbing noise contributes.

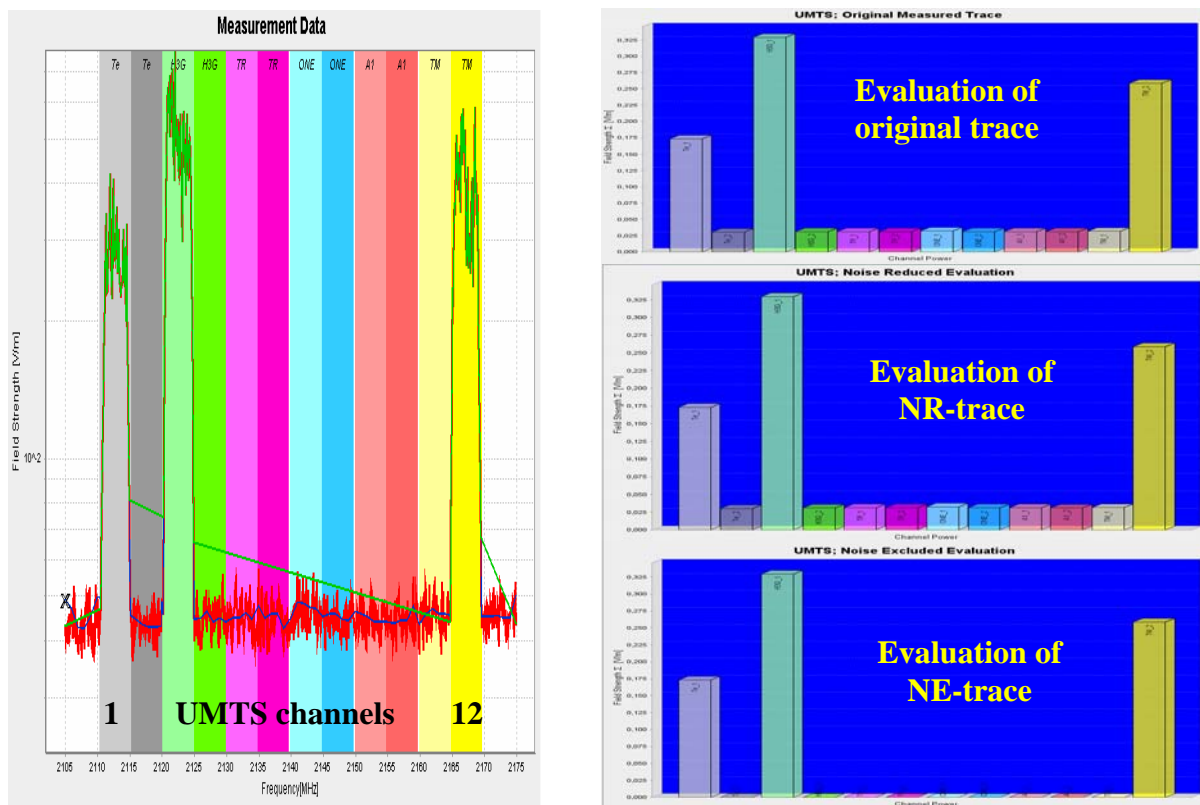

Figure 6: UMTS-DL traces and corresponding channel selective evaluation results

V. Results

Figure 7 is showing 4 original measurement traces and the noise excluded traces after implementation of the algorithm to the original measurement traces. At the top there are typical GSM900-DL measurements performed from 930 MHz to 960 MHz. The left one was made in the rural environment at Seibersdorf and the right during an EMC-exhibition at Stuttgart in 2005. Below them there are 2 of the overview measurements corresponding to

the measurements described in Figure 3. The left one is again from Seibersdorf and the other one from the centre of Vienna. These 4 pictures are showing typical traces which are used to investigate the efficiency in data reduction of the presented algorithm. The results are given in Table 1 for one, ten and fifty similar measurement traces (repetitions) for each of the 4 signal groups.

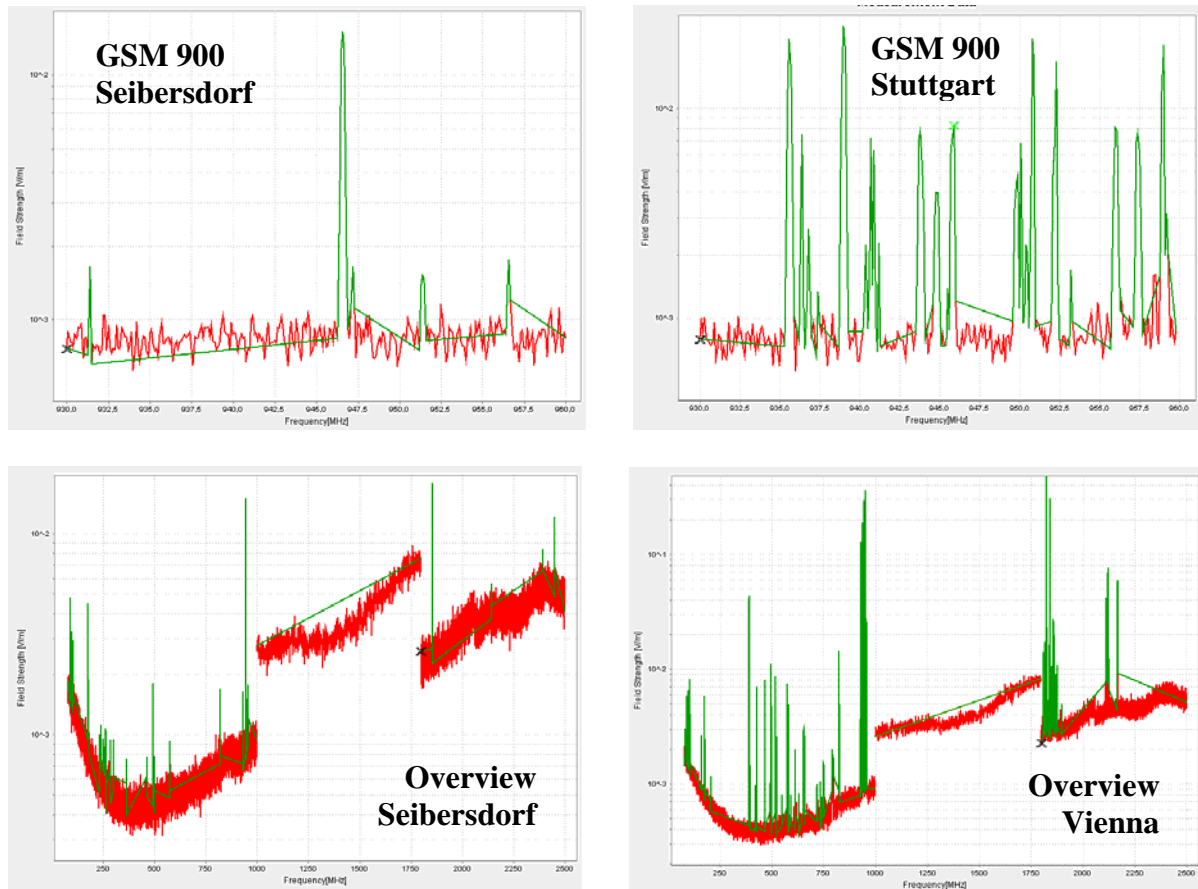

Figure 7: Example traces for the evaluation of Table 1

The values given in percentage are relating to the original measurement traces and give the amount of needed disk space after data reduction. That means a number of 30 % corresponds with a data reduction of 70 %. For the original measured traces the necessary disc space to save the measurement including all settings, factors and other useful information is given in kByte.

	Signal Group	GSM 900; Seibersdorf	GSM 900; Stuttgart	Overview; Vienna	Overview; Seibersdorf
1 Trace	Original Sig. [kB]	9	9	178	178
	NR [% of the original sig.]	77,8	77,8	19,7	14,6
	NE [% of the original sig.]	66,7	77,8	8,4	3,9
10 Traces	Original Sig. [kB]	34	34	1721	1721
	NR [% of the original sig.]	52,9	61,8	12,9	12,3
	NE [% of the original sig.]	32,4	44,1	1,8	1,6
50 Traces	Original Sig. [kB]	140	140	8515	8515
	NR [% of the original sig.]	54,3	59,3	12,3	12,1
	NE [% of the original sig.]	32,9	37,9	1,6	1,5

Table 1: Efficiency of the data reduction algorithm (Noise Height factor = 5dB and 90 % Reduction Value)

As expected the best results are given for overview measurements in a rural environment like Seibersdorf. There are only a few signals present and the noise reduction is very efficient with up to 87,9 % data reduction for the noise data reduced traces and up to 98,5 % for the noise excluded traces at 50 repetitions. That means that the needed disc space is reduced from about 8.5 MByte to less than 130 kByte. This is a data amount which can be processed easily within short time by computers. Also for the noise excluded wideband trace performed in the city of Vienna the reduction is quite similar with 1.6 % of remaining data instead of 1.5 % like Seibersdorf. For the scenario of 288 wideband traces during one day as assumed in chapter III including the evaluation problematic for frequency selective measurements, a total disc space of about 620 kByte would be generated if the presented algorithm is used. This data amount is still not a large problem to process at modern PCs and therefore in fact this algorithm supports frequency selective EMF-measurement systems to overcome the problematic of time delay caused by too much data generation. For a single overview trace the efficiency of the data reduction is a little bit less because of the data overhead necessary for each measurement job independent of its number of repetitions but with about 80 % to 95 % still excellent. For the GSM900 evaluations the reduction of data is from about 22 % for noise reduced signals for one single trace up to 77 % at the 50 noise excluded traces for the GSM900 band at Seibersdorf, but the absolute amount of data is much less than for the overview measurements and therefore not a problem in processing. In addition to that it is a big advantage of the algorithm too, that it is working automatically as a selector to differ between the existing signals and noise, which is not of interest. Only pure signal information is kept in opposite to other methods like band-selective methods or by wideband measurements using field probes where signal and noise is mixed without any possibility for differentiation.

VI. Conclusion

Recapitulating it was found that especially for wideband measurements with a lot of repetitions the presented algorithm has its best efficiency with typically more than 98 % of data reduction for the investigated traces and measurement settings. This enables frequency-selective measurements for sophisticated single investigations on site as well as for long-term monitoring e.g. for dosimetry studies. Caused by the fact that the data reduction algorithm can automatically be applied in real-time to the measured data and it is not specific for any spectrum analyser, it could be used generally for data reduction purposes. Another big advantage of that data reduction process is the differentiation between signal and noise. This enables the user to define the pure signal power for EMF-evaluation instead of a mixture of signal and noise contributes. Furthermore the frequency selective measurement method is still the most sensitive procedure which allows best isotropic behaviour, sharp frequency differentiation and accurate uncertainty estimation. Drawbacks of those systems are the relatively high cost, large mechanical dimension of the some equipment and typically the engineer needs measurement expertise and experience to perform well suited settings that the advantages of frequency selective systems could be utilized.

1. INTRODUCTION

Our group has since 1988 studied the effects of different intensities and modulations of 915 MHz RF in a rat model. In series of more than 1600 animals, we have proven that subthermal energies from both pulse-modulated and continuous RF fields including those from real GSM mobile phones - have the potency to significantly open the BBB

for the animals own albumin (but not fibrinogen) to pass out into the brain and to accumulate in the neurons and glial cells surrounding the capillaries. These results are duplicated recently in another laboratory [1]. Similar results are found by others [2]. In a recent study, we found signs of neuronal damage in the rat 28 and 50 days after a 2 hours exposure for GSM microwaves at 900 MHz with SAR < 0.2 W/kg [3,4].

2. OBJECTIVE

To investigate in the rat the occurrence behavioral changes, leakage of the blood-brain barrier and of neuronal damage after a one year period of weekly 2 hour exposures to radiation from a GSM mobile phone at different intensities.

3. METHODS

48 male and female Fischer 344 rats were exposed or sham exposed for two hours once a week for 55 weeks in TEM-cells to radiation from a software programmable GSM-900 mobile telephone. The animals were awake during the exposure and could move and turn within the exposure chamber. The peak output power fed into the TEM cells were 5 or 500 mW, resulting into average whole body specific absorption rates of 1 or 100 mW/kg. A further 8 animals served as cage controls: The latter stayed undisturbed in the animal facility during the whole period of the investigation. 3 weeks after the last exposure, all animals were subjected to two different behavioral test: (i) the Open Field

test for testing exploratory and motor behavior as well as anxiety, and (ii) the Episodic-like memory task for testing episodic memory and novelty preference [6]. After the behavioral testing period, the animals were anaesthetized and sacrificed by perfusion-fixation with 4% formaldehyde. Brain slices were stained for RNA/DNA with cresyl violet and HSP70 for heat shock protein. Applying albumin antibodies (Dakopatts), albumin in the brain tissue and albumin uptake into neurons is revealed.

4. ANALYSIS and RESULTS

The occurrence of blood-brain barrier leakage and damaged (dark) neurons in different parts of the brain were judged semi-quantitatively by the neuropathologist. No increased number of albumin foci or dark neurons were found in exposed animals as compared to sham-exposed. The Open Field test revealed no effect of exposure on exploratory and motor behavior. The episodic memory test revealed worse short-term memory for exposed animals as compared to sham exposed animals.

Abstract

Merely electric field exposure is often occurred by electric transmission lines, electric appliances without current flow. The aim of this study was to investigate the effects of a 50 Hz electric field on peripheral nerve regeneration in rats. The exposure system was based on parallel-plate-capacitor system. Electric field exposure set-up was established for studies on forty male Sprague-Dawley rats. The rats were randomly divided into four groups each containing 10 rats. Four groups examined variables associated with the method and timing of surgical repair, the arrest of Wallerian degeneration, and the role of electric field in functional recovery. Treatment group1, treatment group 2 and treatment group 3 were subjected to electric fields of 10 kV/m strengths. Control group were subjected to the same procedure, but with the device not activated. The ambient temperature and relative humidity percent of the room housing this facility were maintained at 24 ± 2 °C and 55 ± 5 respectively. Standard poly-carbonate animal cages with PVC lids were kept between the parallel plates producing vertical component of electric field for exposing the animals. The duration of exposure of rat was 1 months. Treatment group1, treatment group 2 and treatment group 3 showed that a vein-graft conduit did not improve functional recovery compared with standard epineurial repair. Also, delayed repair compared favorably with immediate repair.

Key words: Electric field, parallel plate, peripheral nerve regeneration

Introduction

Extremely low frequency (ELF) electric field (EF) and electromagnetic field (EMF) were demonstrated to affect biological systems in vitro and in vivo [World Health Organization, 1984]. Unlike the ionizing radiation and radiofrequency waves, the energy transferred to the biological tissues by the ELF fields is no significant. Some biological processes may be more sensitive than others to ELF EMFs resulting in measurable outcomes.

Weak DC EF was applied to accelerate nerve regeneration following different peripheral nerve injury models [Politis et al., 1988; Kerns et al., 1991; Kerns and Lucchinetti, 1992]. Pulsed electromagnetic field (PEMF), as a non-invasive modality was also effective in enhancing nerve regeneration [Ito and Bassett, 1983; Orgel et al., 1984; Siskin et al., 1989; Walker et al., 1994].

The sinusoidal AC magnetic field was found to accelerate nerve regeneration following a crush injury [Rusovan and Kanje, 1991]. To our knowledge, how ELF EF affects nerve regeneration has not been studied before. Animal studies focused on the magnetic field components, whether they investigate hazards or benefits associated with ELF EMFs. The theoretical background is that the magnetic field is almost unperturbed by tissues as opposed to EFs. Magnetic field is created when electric current flows. EF represents the force that a charge exerts on other charges and a potential difference is sufficient for its presence even when a current does not flow. Pure EFs may have biological effects [Repacholi and Greenebaum, 1999].

Materials and Methods

In this study the experiment was performed on forty young adult, male Sprague–Dawley rats weighing 180–240 g. The study was approved by the Institutional Review for Animal Research Board of SDU and conducted in accordance with the institutional guidelines. The rats were randomly divided into four groups each containing 10 rats. Four groups examined variables associated with the method and timing of surgical repair, the arrest of wallerian degeneration, and the role of electric field in functional recovery. Treatment group 1, treatment group 2 and treatment group 3 were subjected to electric fields of 10 kV/m strengths. Control group were subjected to the same procedure, but with the device not activated. The ambient temperature and relative humidity percent of the room housing this facility were maintained at 24 ± 2 °C and 55 ± 5 respectively. Standard poly-carbonate animal cages with PVC lids were kept between the parallel plates producing vertical component of electric field for exposing the animals. The duration of exposure of rat was 1 months.

Surgical Procedure

The animals were anesthetized by intraperitoneal injection of ketamine (90 mg/kg) and xylazine (6mg/kg). By using a surgical microscope common peroneal nerve was isolated through a short lateral thigh incision on the left side. Two centimeters proximal to its entrance into the lateral crural compartment, peroneal nerve was crushed twice with a no. 3 jeweler's forceps for 30 s, so that only a transparency of the neural sheath was seen at the injury site.

Electric Field Application Set Up

The theory of EF between the plates of parallel plate capacitors was utilized for EF exposure settings [Lorrain and Corson, 1970]. The setup was schematically illustrated in Figure 1. The EF strength was calculated according to the equation $E=V/d$ where V is electric potential between the plates, d is the distance, and E is the EF intensity in volt/meter. Plates were made of a perfect conductor for free charges to disperse homogeneously in order to produce uniform EFs. Zinc plated tin sheets of 2 mm thickness were selected for this purpose. Plates of 50X100 cm in dimension were cut out of them and perfectly flattened. The corners were rounded to get rid of corruptions due to end effect. They were placed upright on wooden stands and positioned parallel to each other. In order not to disturb the field, leads were connected to the center of the plates on their outer sides.

The plates were spaced at 50 cm in distance. Three ungrounded plastic cages were placed inside as seen in Figure 1. Three or four rats were housed in each cage. Cages were in adequate size to ensure free movement of rats and hence homogenous shielding of each other. In addition to weekly cleanups of the plates and cages, the setups were frequently scrutinized for gross soil and wetness that would disturb the homogeneity of EF. The attenuation due to routine soiling could be estimated to cause very small variation in EF. From the equation above, average EF densities between the plates were calculated to be $5000 \text{ V}/0.5 \text{ m}=10000 \text{ V/m}$ (10 kV/m) in 50 Hz groups. Max 3000 TRMS Multimeter (Chauvin Arnoux, Paris, France) was used for voltage measurements.

Figure 1. The electric field application set up.

Discussion and Conclusion

International standard commissions (ICNIRP, IEEE) are generally warn about magnetic radiation to public. General consensus that is below 10 kV/m will be harmless. In this study we tried to show that pure electric field was able to affect on a living tissue.

We designed the study to determine whether any changes occur in the rate of nerve regeneration when rats are continuously exposed to strong EFs for 4 weeks following a crush injury. Treatment group1, treatment group 2 and treatment group 3 showed that a vein-graft conduit did not improve functional recovery compared with standard epineurial repair. Also, delayed repair compared favorably with immediate repair. All differences found between the exposure groups of this study were in accordance with lower rates of Wallerian degeneration and nerve regeneration in 50 Hz EF group.

However, their concordance in direction of effect with each other suggests that continuous 50 Hz EF exposure has a weak effect that is detrimental mostly to the rate of early nerve regeneration in a crush injury model. Although the internal EFs induced by 50 Hz EF in this study are estimated to be within the lower limits of endogenous noise. This suggests that electric induction may be required for pure EF effects even though the density of induced fields is not above the endogenous background level.

The influence of Pulsed Magnetic Fields (PMF) on the synaptic transmission and on the action potential in the mouse nervous system.

Zaghloul Ahmed² and Andrzej Wieraszko^{1,2},

¹Department of Biology/CSI/IBR Center for Developmental Neuroscience, The College of Staten Island, City University of New York, ² Ph.D. Program in Biology, The Graduate School and University Center of NY, New York.

Abstract

We demonstrated previously that exposure of brain tissue to pulsed magnetic fields (PMF) significantly amplified the magnitude of the evoked potentials. Either increase in the amplitude of the action potential, or amplification of the synaptic efficiency could explain observed results. Further investigation revealed, that Paired Pulse Facilitation (PPF), a form of synaptic plasticity observed in the central nervous system was significantly modified by the exposure to PMFs. Although these results pointed at the synapse, as the site of PMF action, the enhancement of an antidromically evoked potentials, recorded from hippocampal slices implied, that PMF can influence nonsynaptic mechanisms as well. This assumption was supported by PMF-induced amplification of the action potential recorded from isolated, peripheral mouse nerve in vitro. It has been determined, that PMF reduced the axonal threshold, making nerves more excitable. Additional studies demonstrated, that the action of PMF is exerted by modifying the action of ion channels, responsible for synaptic transmission and generation of an action potential. The action of PMF was very specific and related to their frequency.

Introduction.

Our previous investigation revealed that Pulsed Magnetic Fields (PMFs) increased neuronal activity recorded from mouse hippocampal slices (Wieraszko et al., 2005). The enhancement in the activity of the nerve cells was expressed as an increase in the amplitude of electrophysiologically recorded evoked potentials (Wieraszko, 2004), which was correlated with an enhancement of the release of neurotransmitter (glutamate) (Wieraszko et al., 2000), and an elevation in the concentration of the second messenger, cAMP (Hogan and Wieraszko, 2004).

The intensity of neuronal activity was measured as the amplitude of the population spike (PS), which represents synchronized firing of the pyramidal neurons (Andersen et al., 1971). While the population spike illustrates synaptic activation of neurons, it has to be preceded by the action potential generated non-synaptically. The diagram in Fig 1 shows the sequence of these events. Presynaptic action potential, induced by stimulating electrodes (S), propagates towards the end of the axon and initiates the release of the neurotransmitter (glutamate in our preparation) at the presynaptic terminal (Pre). The neurotransmitter released from the presynaptic part stimulates the postsynaptic part (Post), generating population spike (potential # 3). The same stimulation can also generate the action potential, which will propagate toward the cell body of neuron A initiating antidromically evoked potential # 1. No synaptic transmission is involved in generation of this potential. Therefore, the influence of PMF on both: 1) the presynaptic mechanism of generation of an action potential and, 2) synaptically mediated mechanism of generation of the population spike may contribute to the PMF-induced modifications of the amplitude of the population spike. The purpose of the current research was to evaluate the contribution of the presynaptic and postsynaptic mechanisms in modulation of the population spike by PMF.

Fig1. The diagram of neuronal activities recorded in the experiments on hippocampal slices. Stimulating electrode (S) initiates the generation and orthodromic propagation of an action potential # 2. This potential reaches the nerve terminal (Pre) stimulating the release of neurotransmitter (N), which activates postsynaptic part initiating generation of the population spike (potential # 3) in neuron B. Thus, the population spike (potential # 3) is generated, as a result of presynaptic and postsynaptic activities. The action potential initiated by stimulating electrode (S) can also propagate towards the cell body of neuron A (antidromic stimulation) generating an action potential # 1. This potential is generated without the involvement of synaptic transmission.

While the mouse hippocampal slices were used to evaluate the involvement of presynaptic and postsynaptic mechanisms, the segments of the mouse sciatic nerve were used to verify the results related to presynaptic component.

Methods

The biological preparation (hippocampal slices, or segments of sciatic nerve) have been incubated in a chamber shown in Fig 2, and exposed to pulsed magnetic fields for 30 minutes. The evoked, neuronal activity of the preparation was followed before, during and after exposure to PMF.

PMF exposure

The pulsed magnetic field (PMF) was generated by DC-powered coils (Trabulsi et al., 1996; Wieraszko, 2004), wound around an acrylic frame, which surrounded the interface-recording chamber. The activation and deactivation of the coils was operated by a programmable timer, which was set at different frequencies to meet the goal of the specific experiment. A plastic tube connected to the building air supply secured the flow of the air indicated by arrows E. The flow of air prevents the water chamber from overheating during electromagnetic field activation (Trabulsi et al., 1996; Wieraszko, 2004) (Fig 2). Regardless of the frequency of the pulsed magnetic field, each pulse has four phases: rising phase (period of coils charging), static magnetic field phase (period of no change; the power supply on), falling phase (period of coils discharging), and then an "off" phase (power supply off), (Fig 3 and 4). The duration of the rising and falling phases (measured as shown in Fig 4) was equal for all frequencies generated by our magnetic field setup; however, the number of these phases is substantially different for different frequencies. Unless specified otherwise, the frequency that was used was 0.16 Hz. The same field was used for hippocampal slices and for sciatic nerve preparation. The one "on" and "off" period was considered as one cycle and the frequency of magnetic field stimulation was expressed as number of these cycles per second (Fig 3). The graph in Fig 3 shows magnetic field pulse recorded on-line for the

Fig. 2. A diagram of the experimental system. The slice (A) is placed in the chamber (B) that is filled with Ringer's solution and oxygenated with 95%/5% O₂/CO₂. The water chamber (C) contains the temperature sensor (H) and the oxygenating airflow. The magnetic coil (M) encircled the acrylic frame (D). During the magnetic field application, airflow circulating through a holed tube (K) is turned on, creating an air flow (E) to dissipate any accumulated heat. (According to Wieraszko, 2004).

period of thirty minutes. Neither change in the PMF strength nor shape was observed. A, B and C show on-line PMF recording for 4 minutes in the beginning, middle, and at the end of thirty minute period.

Fig. 3. Thirty minutes of PMF recording. This graph shows - on line - magnetic field pulse recording for the period of 30 minutes that illustrates neither change in the PMF strength nor shape. A, B and C show on-line PMF recording for 4 minutes in the beginning, middle, and at the end of 30 minutes.

Fig. 4. A photograph of the PMF pulse taken from oscilloscope screen. It shows the rising (R), and falling phases (F). The white vertical lines and horizontal lines (T) were drawn to calculate the slope of the rising and falling phases of magnetic pulse (black trace). The duration of the "on" phase, and the intensity of the field shown on this photograph is 3 sec. and 15 mT, respectively.

Results

A. The influence of PMF on synaptic and nonsynaptic component of neuronal activity tested on hippocampal slices.

The hippocampal slices were prepared from CD-1 strain of mice, as described previously (Wieraszko,

Fig. 5. Hippocampal pathways and recording of their activities. The diagram shows the hippocampal pathways and the location of stimulating and recording electrodes. The electrode stimulating orthodromically is located in CA3 hippocampal subfield. When activated, it evokes the action potential, which propagates towards CA1. This action potential, in turn, synoptically activates CA1 pyramidal neurons, which generate population spike. Pyramidal neurons can be also stimulated nonsynaptically with antidromically stimulating electrode.

1983). The diagram of the cross-section of the hippocampus is depicted in Fig 5. The population spike can be evoked by either orthodromic stimulation of the Schaffer collateral and then recording from the CA1 pyramidal cell layer (this involves synaptic transmission), or by the antidromic stimulation, which is defined as the stimulation of the axonal area of the CA1 and recording from CA1 pyramidal cell layer (it does not involve synaptic transmission). See also Fig 1 for further explanation.

A.1. Effects of PMF on paired pulse facilitation (PPF)

Our previous experiments (Wieraszko, 2004) demonstrated a PMF induced increase in the magnitude of the population spike evoked by single-pulse electrical stimulation applied at the frequency of 0.16 Hz. To analyze this phenomenon further we applied paired-pulse stimulation paradigm, which is considered a good indicator of the changes in the mechanism of orthodromically induced synaptic processes of the neurotransmitter release. Two pulses, separated by the interstimulus interval of 15-55 ms were applied with the frequency of 0.16 Hz to evoke two population spikes. Paired-Pulse Facilitation (PPF) was expressed as an increase in the magnitude of the second population spike as compared to the first one. PPF was calculated as the difference in amplitude between the first population spike (PS1) and the second population spike (PS2). An increase in the second population spike relative to the first will produce higher PPF. The expression of PPF as the difference rather than the ratio has been chosen, since PMF increased both PS1 and PS2 (Fig 6). The experiment was initiated by recording of the PS for 20 minutes prior the exposure to PMF (baseline). The average of the PPF measurements that were calculated from the baseline period was compared to the averages taken from the recordings after the exposure to PMF. The result of ten experiments showed significant increase in PPF after the PMF exposure ($n=10$, 150 %, $p=0.000317$, paired sample t test was used). Note, that although the magnitude of both population spikes increased following PMF exposure, the facilitation of the second one exceeded the facilitation of the first (Fig 6).

Statistical analysis revealed, that there was no correlation between initial PPF and the change in the amplification of PPF. Therefore we assumed, that the amplification of PPF was not due to PMF-

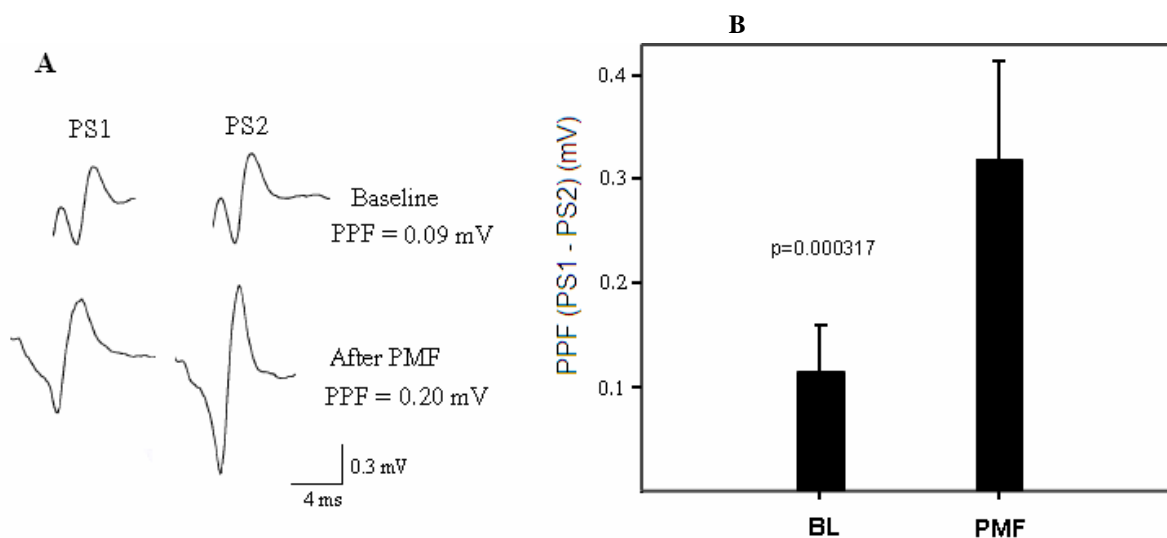

Fig. 6. The influence of PMF on paired pulse facilitation. A - Potentials marked PS1 and PS2 correspond to the first and second evoked potentials, respectively and were initiated by two consecutive pulses applied with a frequency of 0.16 Hz; inter pulse intervals (IPI) was adjusted accordingly to get the largest PPF (25 – 55 ms). The PPF was calculated as PS2 minus PS1. The upper and lower potentials represent potentials that were recorded during the baseline and after the PMF exposure, respectively. PPF was increased by about 120% after the exposure to PMF. Note, that both PS1 and PS2 increased after exposure. B - the average changes in PPF after the exposure to PMF applied at the frequency of 0.16 Hz ($n = 11$). The baseline bar (BL) represents the average of PPF from the first 10 - 15 minutes before the application of PMF. The PMF bar represents the average of PPF during maximal effect of PMF amplification. The result of the paired t test is shown in the graph.

The influence of magnetic fields on the nervous tissue

induced increase in the number of firing neurons, but due to an increase in the excitability of the same population of neurons, which were active before PMF exposure.

A.2. The effect of PMF on antidromically evoked population spike in the hippocampal slices

To inquire into the mechanisms of PMF, we considered an experimental paradigm that would express the action potential without concomitant involvement from synaptic transmission. Stimulating the hippocampal pyramidal cell layer CA1 with antidromic stimulus (stimulating electrode on the subiculum,

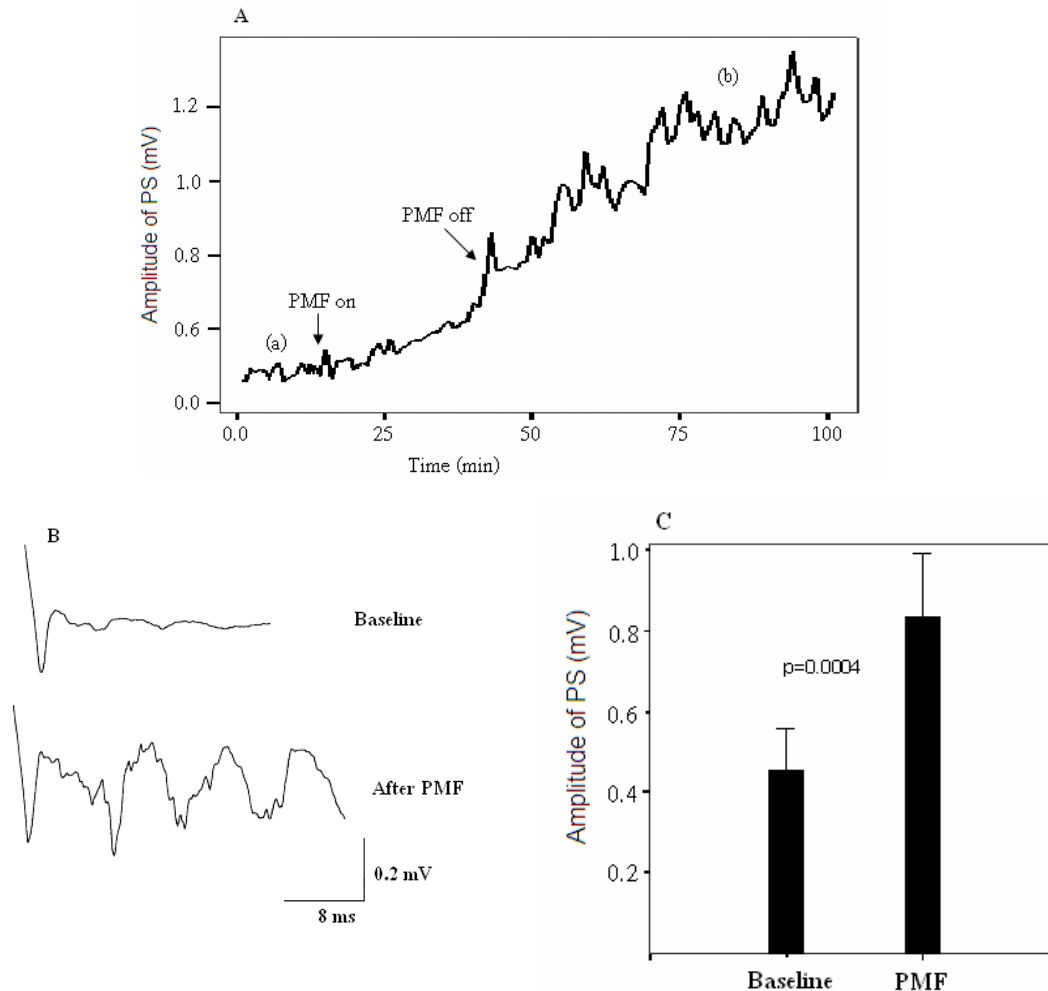

Fig.7. The effect of PMF on the antidromically evoked population spike. The slices were incubated in a calcium free medium and with 2mM kynurenic acid. A – a representative experiment showing the amplitude of the population spikes before (a) and after (b) the application of PMF. B – A waveform that shows the potential amplitude before and after PMF exposure; note the generation of multiple potentials . C – Average results of baseline and at maximal PMF effect ($n = 15$, $p = 0.0004$). Paired t test was used.

recording electrode on the pyramidal cell layer CA1) (Fig. 1 and 2) would induce pre-synaptic action potentials only. The addition of kynurenic acid (a blocker of glutamergic receptors) to the slice containing chamber and the omission of calcium would eliminate any contribution of glutamergic synaptic transmission to either the initiation or size of recorded potentials. Fifteen experiments on 15 different slices taken from 5 animals were performed. The potentials were recorded for 20 minutes to create a stable baseline, and then a PMF of 0.16 Hz was turned on for 30 minutes. Averages from the baseline and at the maximal effect of PMF (20 potentials) were compared. The PMF has not only

increased significantly the size of population spikes ($n=15$, 183.3%, $p=0.0004$, Fig 7A, B) but also induced multiple firings and seizure like activity (Fig 7 B). There was no correlation between the amplitude of the baseline and the amplitude of the change (the PS amplitude after PMF exposure minus the PS amplitude of baseline) after the exposure to PMF. That means that the effect of PMF was independent of the amplitude of the initial population spike.

B. The influence of PMF on the action potential recorded from the sciatic nerve.

CD-1 strain of mice was used to prepare segments of sciatic nerve. Following decapitation both hind limbs were skinned. The upper thigh muscles were then cut and either the femoral bone was broken or the hip joint was dislocated. The broken limb was pulled away and muscle tissue of the thigh were cut to expose the sciatic nerve from its origin in the vertebral column. The two ends of the sciatic nerve were cut and the nerve was pulled out and placed in the ice-cold Ringer's solution. The nerve was then cut into 4 to 6 mm segments, which were placed in an incubation chamber maintained at 33°C, and constantly oxygenated with a 5%/95% CO₂/ O₂. The individual segment was transferred in turn into a recording chamber. The epineurium (the outermost layer of connective tissue surrounding the entire peripheral nerve) remained intact. The recording electrode was placed inside the epineurium at the end of the cut and the stimulating electrode was placed out side the epineurium at a distance that was varied to obtain the robust compound action potential (CAP) (Fig 8).

Fig. 8. The placement of the electrodes on a sciatic nerve segment.

B.1. Effects of PMF on compound action potential (CAP)

It can be surmised from the preceding experiments that the PMF effect probably influences the mechanism of action potential through changes in its initiation and propagation. Therefore, we decided to investigate the effect of PMF exposure on the sciatic nerve, which represents simpler preparations without any synaptic connections. The interpretation of the PMF-induced effect could then be circumscribed to the processes responsible for generating, modulating and propagating action potentials. To investigate the effect of PMF on the compound action potential recorded from the sciatic nerve, 10 experiments were performed. A typical experiment is depicted in Fig 9. The averages of the CAP amplitude recorded in the first 20 minutes (baseline), were compared to the averages of the CAP amplitude recorded 30 minutes after the exposure to PMF. The PMF increased the mean amplitude of the CAP significantly ($n=10$, 187.1%, $p = 0.005$, Fig 10). Control experiments revealed, that the amplitude of CAP remained constant for at least 2 hrs, when PMF was not applied. The PMF-induced amplification of the amplitude of the compound action potential occurred independently on electrical stimulation used to induce neuronal activity. When the electrical stimulation was discontinued during PMF exposure, there was still an increase in CAP amplitude (Fig 11).

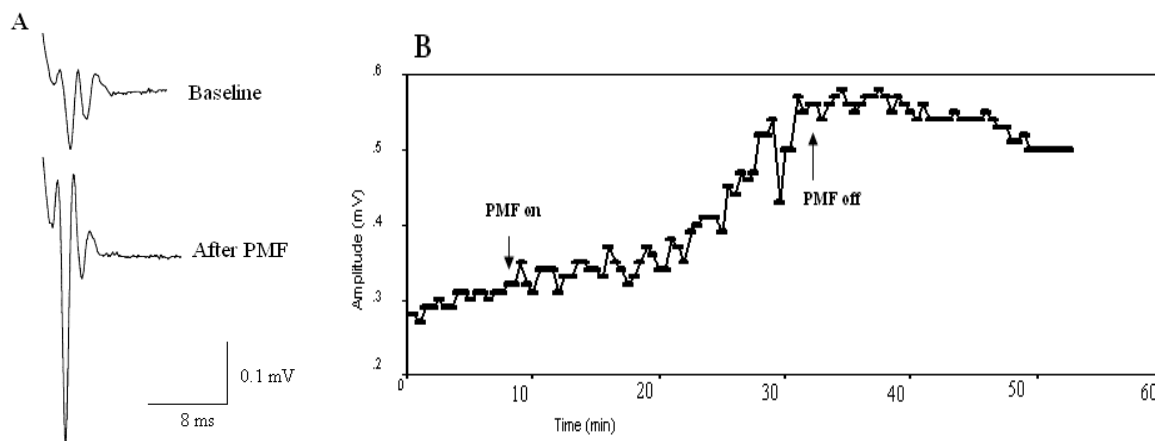

Fig. 9. A representative experiment demonstrating the influence of PMF on CAP. A – The upper and lower potentials represent the CAP before and after PMF exposure, respectively. B – the change in the amplitude of CAP during entire experiment; "PMF on/PMF off" indicates initiation and termination of the magnetic field exposure, respectively.

Fig. 10. The influence of PMF on CAP recorded from the sciatic nerve. The bars show the averages of 10 experiments, performed on ten different segments of the sciatic nerve prepared from eight mice. BL refers to the baseline-recording period. The PMF bar represents the recordings at the maximal effect of the PMF. PMF significantly increased the compound action potential ($n=10$, 187.1%, $p = 0.005$). Wilcoxon signed ranks test, for 2 related samples was used.

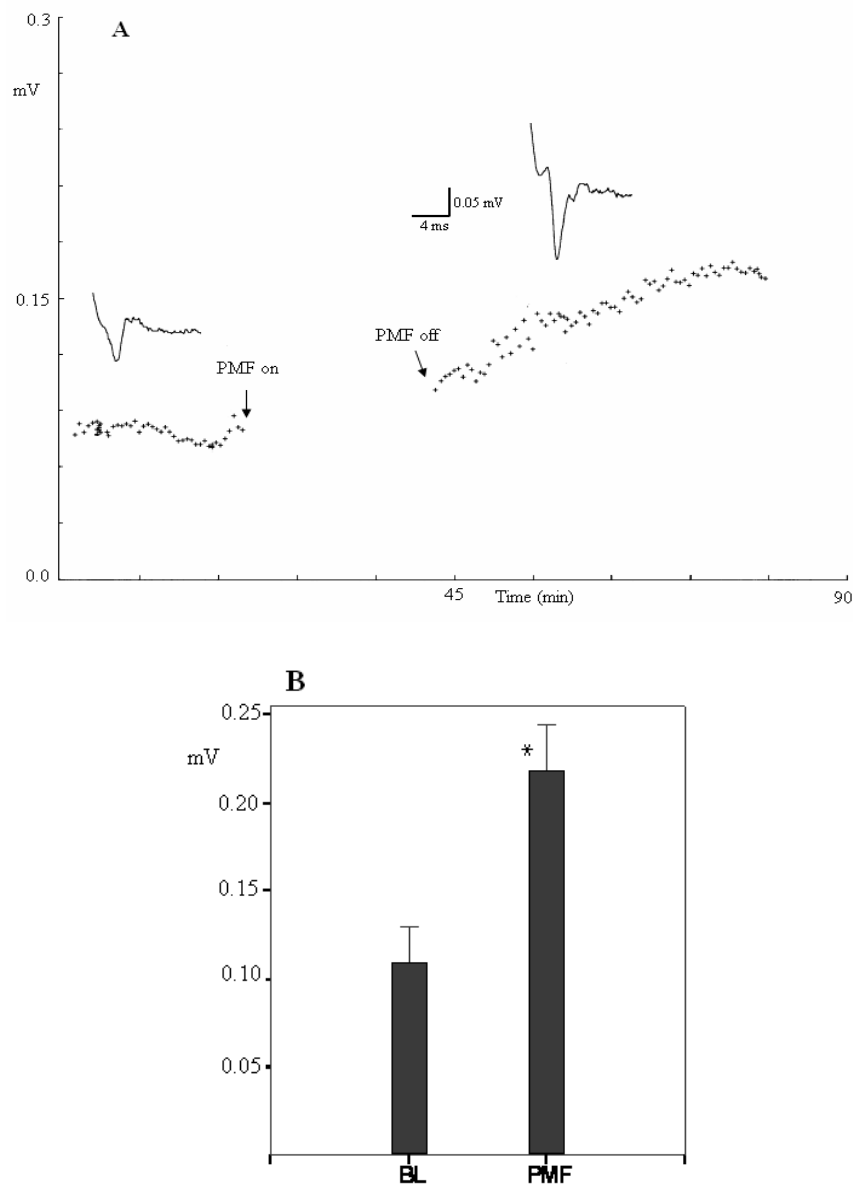

Fig. 11. PMF effect was independent of the concurrent electrical stimulation used to evoke CAP. The recording was followed for 20 minutes and then the electrical stimulation was stopped during the 30 minutes exposure to PMF. After the PMF was turned off, electrical stimulation was resumed and potentials were followed for another 30 minutes. A – An example of a typical experiment: the upper part of the graph represent potentials recorded before and after PMF exposure and the lower part of the graph shows the potential amplitude that was followed throughout the experiment except the period of PMF exposure. Note that during PMF exposure no electrical stimulation was applied and no records of CAP were taken. B – Bars represent the averages that were taken from the baseline period (BL) and at the maximal effect after the PMF exposure (PMF). PMF induced significant increase of the CAP amplitude ($n=11$, $p=0.002$, 185.7%, Wilcoxon signed ranks test).

The influence of magnetic fields on the nervous tissue

We have also investigated the influence of PMF on the axonal threshold. In most of the experiments, 0.1 V was the lowest strength used to evoke the lowest compound action potential, and for maximal strength one Volt was used. Any stimulus strengths above one Volt were considered supra maximal. During the baseline period of each experiment, one recording was taken at the strength of each stimulus and repeated after the PMF exposure. Note that the same electrical stimulus strength evoked higher CAP amplitude after the PMF exposure. Figure 12 shows that the PMF reduced the threshold

Fig. 12. Effects of PMF on the sciatic nerve threshold. The stimulus strength ranging from 0.1 V to 4.5 V was applied to the sciatic nerve preparation before (● ●) and after (▲ ▲) the exposure to PMF. Eight measurements (one measurement at each value of stimulus strength) were taken from each experiment before PMF exposure (solid circles) and another eight measurements were taken after the PMF exposure (solid triangles). The PMF shifted the threshold curve to the left, which suggests reduction in the axons threshold. That left shift was statistically significant in all stimulus strength values ($p < 0.05$, $n = 8$) except at 0.1V ($p > 0.05$, $n = 8$, paired Samples t test). Each point on the graph represents the average of eight experiments.

significantly ($n = 9$, $p < 0.05$) in all stimulus strengths except at 0.1 V, where the reduction of the threshold was small and statistically insignificant ($p > 0.05$).

B. 2. The effect of PMF on sodium channels

The experiments previously described, suggest that Na^+ and K^+ channels are involved in the mediation of the PMF-induced effect. Therefore the effects of PMF on CAP was studied in the presence of 10nM TTX (a potent sodium channel blocker).

After stable baseline recordings were established, TTX (10nM) was added to the recording chamber. TTX significantly reduced the CAP amplitude ($p = 0.009$, 68.2%, $n = 6$). Fig 13 A and B show a typical experiment and the average of all data, respectively. When the amplitude of the potential stabilized at its minimum value after the addition of TTX (15 - 20 minutes), the PMF was applied for 30 minutes. The depressive effect of TTX was not only eliminated within first 10 minutes of the PMF application, but was reversed to amplification in the later stages of the PMF exposure ($p = 0.027$, $80\% \pm 55\%$, $n = 6$). Figure 13A shows a representative experiment showing the CAP potentials and the change in their amplitudes depicted as the upper and lower parts of the graph, respectively. The bars in figure 13B represent the averages of potentials recorded during three periods of the experiment: 1) baseline (before the addition of TTX and the PMF exposure) marked as (BL); 2) at the maximal of the depressive effect of TTX (TTX) and 3) at the maximal amplification after the PMF exposure (PMF). We have also investigated the effect of the PMF on CAP in the presence of lidocaine, a strong local anesthetic whose action is mediated by the blocking of sodium channel. After stabilization of the potential, lidocaine (150 μM) was added to the recording chamber. It significantly reduced the amplitude of the compound action potential ($p = 0.0005$, $n = 8$). When the amplitude of the potentials stabilized at its minimum value after the addition of lidocaine (15 -20 minutes), the PMF was turned on for thirty minutes. Surprisingly, the

PMF reversed the depressive effect of lidocaine within 7-10 minutes (Fig 14A). The reversal effect of the PMF was significant ($p = 0.0005$, $n = 8$, Fig 14B). Washing away the lidocaine amplified the potential even further ($p = 0.003$, $n = 8$). Figure 14A depicts a typical experiment that shows the potential shape

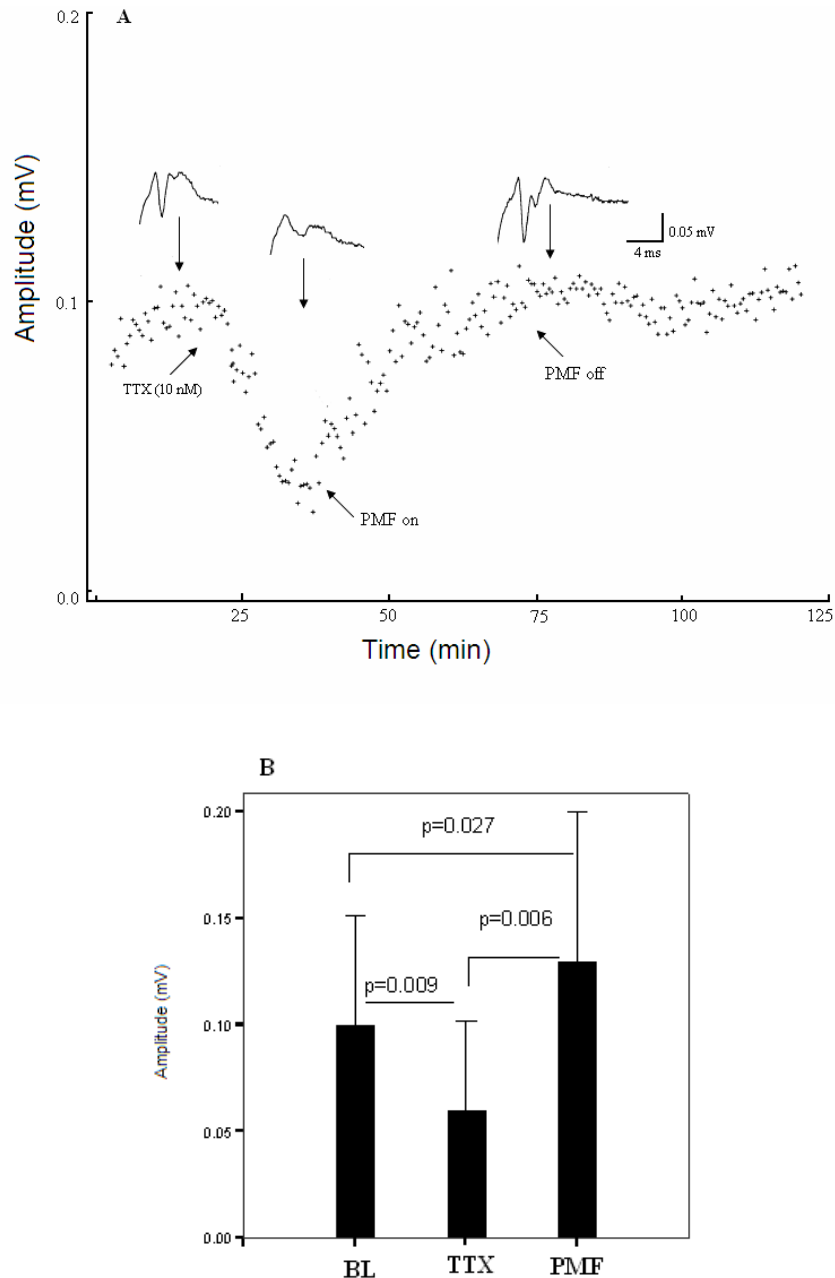

Fig.13. The influence of PMF on TTX-induced depression of CAP. A – A representative experiment. Following 15 minutes of baseline, TTX was added to the recording chamber. TTX reduced the CAP significantly ($p=0.009$, 68.2%). After the recording in the presence of TTX showed stability, PMF was turned on for 30 minutes. It reversed the TTX-induced depression and in later stage it significantly amplified the potential over the baseline. B - the averages of the potentials recorded during different stages of the experiment: the baseline (BL), after TTX addition (TTX) and after PMF exposure (PMF). PMF significantly reversed the effect of TTX and increased the CAP significantly ($p=0.006$, 80%, $n=6$, paired samples t -test).

The influence of magnetic fields on the nervous tissue

and amplitude at different periods of the experiment. Bars in Figure 14B represent the average potential for different periods of the experiments.

In control experiments (no PMF) the potential depressed by lidocaine was followed for over an

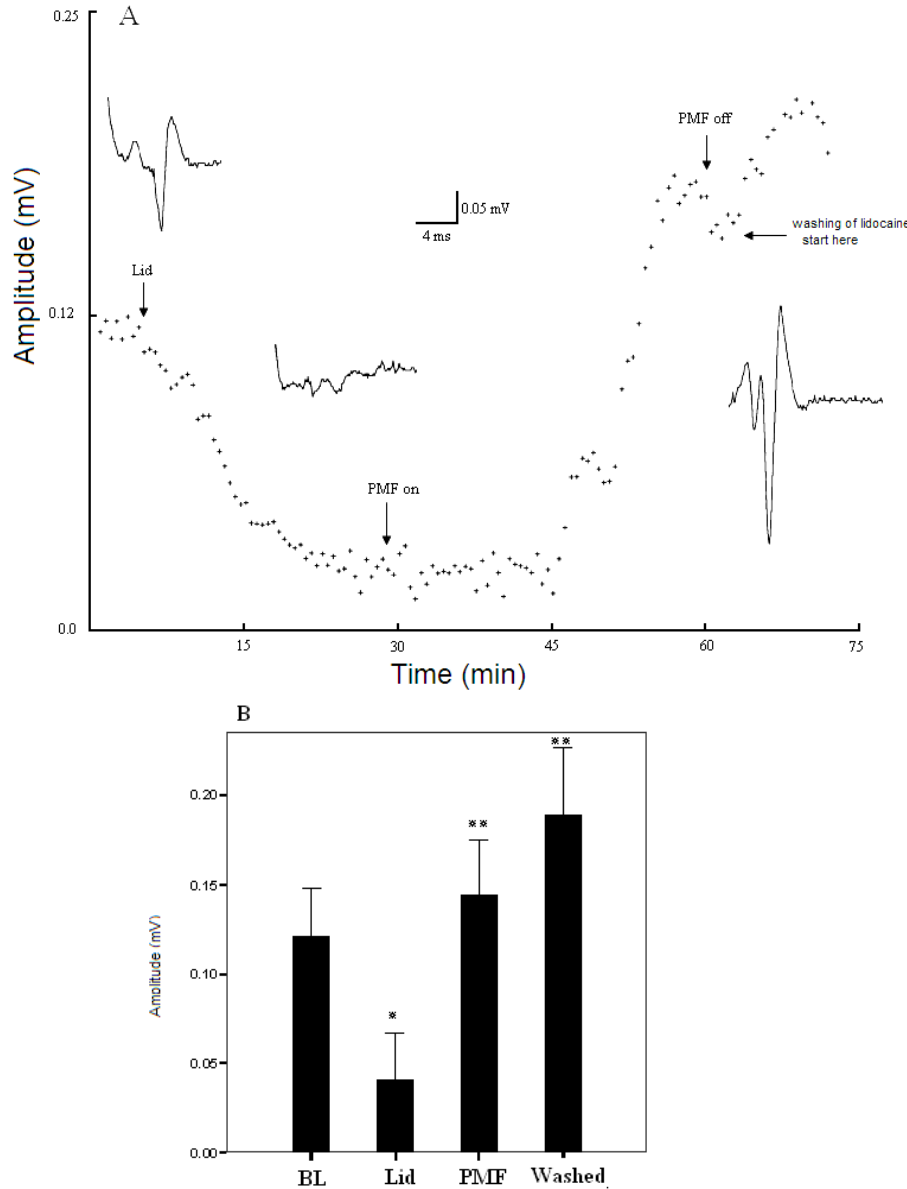

Fig.14. The influence of PMF on lidocaine-induced depression of CAP. A – A representative experiment demonstrating the depression of CAP by lidocaine (150 μ M) and the reversal of lidocaine's action by PMF exposure. B – The magnitude of CAP in baseline (BL), after the addition of lidocaine (Lid), after PMF exposure (PMF), and after lidocaine was washed away (Washed). Lidocaine-induced attenuation of CAP ($p=0.0005$, $n=8$), was reversed by PMF exposure ($p = 0.0005$, $n = 8$, paired t -test). The increase that was induced by PMF exposure was significantly higher than the mean of the CAP of the baseline ($p=0.04$). Washing of lidocaine away induced additional increase in CAP amplitude, which exceeded the value of the potentials recorded after PMF exposure ($p=0.003$). *denotes a statistically significant difference ($p<0.05$) between the baseline and after the addition of lidocaine. **denotes a statistically significant difference ($p<0.05$) between after PMF and after washing and both baseline and lidocaine.

hour and no spontaneous recovery was observed, unless the lidocaine was washed away with fresh Ringer's solution (Fig 14B).

The results of experiments with lidocaine and TTX inspired us to investigate the idea, that PMF amplifies the action potential by modifying the gating process of the sodium channel. To verify our assumption we used veratridine, which modifies inactivation gate and induces a persistent activation of the sodium channel (Hille, 2001). In the sciatic nerve preparation veratridine did not change the size of CAP ($n = 10$, $p = 0.619$) but reversed the action of the PMF from facilitation to depression ($p = 0.002$). These results indicate that the PMF potentiated the effect of veratridine probably by facilitating its binding ability.

B.3. The pulsed magnetic field frequency and its effect on CAP.

We have also investigated the influence of magnetic field frequency on the changes in the CAP amplitude. Five frequencies have been selected: 0.5 Hz, 0.16 Hz, 0.07 Hz, 0.03 Hz, 0 Hz (static). The static magnetic field was used to compare the results obtained on sciatic nerve with our previous data on hippocampal slices (Wieraszko, 2000). Interestingly, although the static magnetic field initially reduced the CAP, ($n = 16$, $p = 0.0009$), it induced recovery/amplification of the potential in the later stage of its application ($p = 0.481$, Fig. 15 and 16). Figure 15 shows an example of a typical experiment that represents the amplitude of the potential, and Fig 16 depicts the potential shape at different stages of the experiment.

Fig. 15. A representative experiment showing the influence of static magnetic field on CAP recorded from the sciatic nerve. Static magnetic field induced biphasic effect: depression phase during the application of field and recovery/amplification phase after the termination of the field.

The influence of magnetic fields on the nervous tissue

Fig. 16. Three waveforms show the shape and the amplitude of CAP: before (1), during (2), and after (3) exposure to the static magnetic field..

The influence of different frequencies of PMF on the magnitude of CAP is shown in Fig 17.

Fig.17. The influence of different frequencies of PMF on CAP recorded from the sciatic nerve. The bars represent the percentage of control calculated as the difference between the average before and after the PMF exposure divided by the average before PMF exposure. The numbers above the bars represent the p value, which was calculated using one sample t test. The difference between groups was statistically significant One way ANOVA was used ($F = 7.566$, $p = 0.0002$).

C. Discussion.

Our findings support our previous reports on the effect of PMF on the nervous system (Trabulsi et al., 1996; Wieraszko, 2000; Wieraszko, 2004; Wieraszko, et al., 2004). The effect was frequency-dependent and mediated by synaptic and non-synaptic mechanisms. The enhancement of the paired-pulse facilitation (PPF) implies PMF-induced modulation of presynaptic mechanism, most likely the processes regulating neurotransmitter release. This supports our previous results demonstrating PMF-induced reduction in glutamate uptake (Wieraszko et al., 2005). One can hypothesize, that PMF-induced decrease in Ca^{2+} buffering, amplification of Ca^{2+} release from the internal stores, and/or increase of the influx of Ca^{2+} through calcium channels at the pre-synaptic terminal may be involved in observed effects.

The result from the experiments with antidromic stimulation of the hippocampal slices provided the first clue toward the axonal involvement in the PMF-induced increase in excitability. When synaptic transmission was blocked, the PMF was effectively inducing an increase in the antidromically recorded population spike. Further analysis of the result of these experiments indicated that the population spike amplification was not due to an increase in the number of firing neurons but resulted from an increase in excitability of the same population of neurons. This assumption was further supported by the experiments performed on sciatic nerve. The compound action potential (CAP), recorded from this preparation was permanently amplified following PMF exposure. This amplification was correlated with PMF-induced reduction in the axonal threshold. The plateau of curve illustrating the relationship between CAP amplitude and the strength of the stimulus was similar in the exposed and unexposed preparations. This supports the conclusion that the PMF-induced increase in the CAP amplitude was due to an increase in excitability of the same population of axons and not by the recruitment of new axons.

PMF has been shown not only to reverse the depressive action of TTX and lidocaine, but to amplify the CAP at a later time in the experiment. Apparently, PMF exposure changed the properties of sodium channel reducing its affinity for both ligands. Local anesthesia drugs such as lidocaine can shed more light on how PMF induced hyperexcitability. In the presence of lidocaine sodium channel inactivation is greatly amplified. Hyperpolarization of the cell membrane is needed to relieve this inactivation of the channel (Hille, 2001). Theoretically, lidocaine binds to a site inside the channel pore and its binding is voltage dependent. Since depolarization is needed for the drug to block the channel, it is assumed that lidocaine binds more tightly to an inactivated sodium channel (Hille 2001). These phenomena can explain why the PMF eliminated the lidocaine effect on sodium channels. Hyperpolarization of the cell membrane by PMF initiates following, sequentially occurring events: 1) it opens the inactivated gate more readily; 2) it loosens drug binding; 3) it makes the drug more prone to site dissociation. However, hyperpolarization cannot alone explain all the PMF induced effects mentioned above, and experiments with TTX suggest that PMF exposure induces also changes in the channel protein conformation. TTX binds to the extracellular site of the sodium channel in a voltage-independent way, blocking stimulated and non-stimulated axons. Since TTX does not react with the channel gating system hyperpolarizing of the cell membrane would not affect the action of TTX. Therefore, the changes in the channel protein conformation, not change in the membrane potential could explain the effect of PMF on TTX-sodium channel interaction.

PMF induced effect was blocked by veratridine. Veratridine reduces the conduction of sodium channel and prevents its inactivation (Hille 2002). The action of veratridine is activity-dependent and it does not affect the activation gate of sodium channels. Veratridine modifies the inactivation gate of sodium channels and the lifetime of that modification is in milliseconds. The reaction of the drug (binding and unbinding) develops from the open state of sodium channel (Hille, 1968; Sutro 1968; Leibowitz et al. 1986; Wang et al. 1990). The dependence of veratridine action on the open state of sodium channel explains the cooperative effect between the PMF and veratridine actions. The PMF increased the rate of activation of sodium channels and that in turn intensified the action of veratridine. Thus, veratridine together with PMF reduced the amplitude of CAP2. Being that PMF did not reverse the action of veratridine, it means that the PMF effect on the shape of the channel protein is specific. If the change in the channel complex is general, it would have affected its affinity to all three antagonists. Instead, the PMF changed the affinity of lidocaine and TTX and reversed their actions, but it did not diminish the affinity for veratridine. Just to the opposite, it intensified its action. This observation points to the probability of the presence of particular sites in the channel complex with different sensitivities to magnetic field exposure.

The influence of magnetic fields on the nervous tissue

Although the PMF used in this study is a very specific form of magnetic field spectrum, the findings and their analysis can be applied as a basis for other magnetic field forms biological effects. Magnetic field in general is approved to be beneficial as an adjunct therapy in medicine (see review by Shupak, 2003). The lack of mechanisms of magnetic field action hindered its research toward therapeutics (Rubik, 1997). Here we introduced a mechanistic basis for their effect, which would help and guide clinicians and researchers to the best possible utilization of magnetic field in the treatment of the pathology. A clinical based research could test the effect of PMF on the peripheral nervous system on humans.

Abstract

During recent years our studies have been focused on the effect of modulated low-level microwaves on human EEG rhythms. In this study the experiments with 450 MHz microwave modulated at 40 Hz and 70 Hz frequencies were carried out on a group of 15 volunteers. The field power density at the scalp was 0.16 mW/cm². Ten cycles of the exposure (1 min on and 1 min off) with each modulation frequency were applied. The energies of 8 EEG channels FP1, FP2, T3, T4, P3, P4, O1 and O2 were analysed for individuals by two different methods: nonlinear method of scaling analysis for length distribution of low variability periods (LDLVP) and relative changes in EEG energy between segments with and without exposure (*S*-parameter). Statistical analysis of the calculated measures with post-hoc Bonferroni correction by approach with a 0.05 confidence level was applied.

The exposure caused increase of the EEG energy; changes were stronger in temporal and parietal regions and EEG beta rhythms. Statistically significant changes in EEG were detected for 4 subjects (26.7%) with 40 Hz modulation frequency. The rate of multiple chemical sensitivity (between 2 and 10 %) is even lower than sensitivity to microwave.

Keywords: EMF effects, nonionising radiation, microwave radiation, time variability, scaling analysis, spectral analysis, EEG rhythms.

Introduction

The nervous system has been thought to be most sensitive to external electromagnetic field (EMF) since there is a tremendous electrical activity in neural processes. Information processing and transmission in nervous system is based on bioelectromagnetic phenomena. Therefore, can be expected that EMF effects at system level appear most likely in nervous system.

Modulated microwave radiation at non - thermal level of field power density can affect human central nervous system in a sensible way. Except in unhealthy artificial conditions the effect is weak and difficult-to-detect. Reports of possible non-thermal EMF effects are often contradictory and the difficulties in independent repeating of the experimental results cause doubts. Mechanisms behind the effects are still unclear. Several investigators have reported that low-level exposure produces alterations in the EEG signal and brain behavior [1 - 7], while others conclude that exposure to electromagnetic field does not alter resting EEG [8, 9].

In our previous studies the relative changes in the EEG rhythms energy caused by microwave radiation modulated inside the EEG physiological spectrum at frequencies 7 Hz, 14 Hz and 21 Hz were investigated [10]. The conclusion was that the effect produced by microwave radiation has a clear frequency dependence and increases with modulation frequency. The influence of microwave with modulation frequency 217 Hz – technical frequency much higher than the EEG rhythms – has been also reported to produce statistically significant changes in time variability and intensity of the EEG signal for 10-20% of healthy subjects [11].

This study is aimed to evaluate the effect of microwave modulated with intermediate frequencies 40 Hz and 70 Hz. The same exposure conditions utilized in our previous studies were applied. Two methods were selected for EEG analysis: scaling analysis of length distribution of low variability periods (LDLVP) as sensitive to signal time variability [12] and relative change in the EEG energy of segments of the signal with and without exposure as sensitive to the changes in signal level [6].

Method and equipment

Subjects

An experimental study was carried out on a group of volunteers. The group consisted of 15 young persons (aged 21-24): 8 male and 7 female. Their physical and mental condition (tiredness, sleepiness) before the experiment was evaluated by a questionnaire and a clinical interview. All the subjects selected were healthy, without any medical or psychiatric disorders; tired or sleepy people were excluded. After the recordings, they described how they felt during the experiment. The subjects reported neither alertness nor any strain experienced during the recordings.

The experiments were conducted with the understanding and written consent of each subject. The study was conducted in accordance with the Declaration of Helsinki and has been formally approved by the local Medical Research Ethics Committee.

The measurements were performed in a dark laboratory, but no other special conditions were provided. The subjects lay in a relaxed position, with eyes closed and ears blocked during the experiments.

All the subjects were exposed and sham exposed. Only one experimental EEG recording was performed for a subject during a day. The measurements were double blinded. During each test session, the exposed and sham-exposed subjects were randomly assigned. The subjects were not informed of their exposure; however, they were aware of the possibility of being exposed. Subjective factors were also excluded from the computer-performed data analysis: the same algorithms were applied for all the recordings (both for exposed and sham-exposed subjects).

Microwave Exposure

The modulated microwave radiation at non-thermal level of field power density, identical to our previous studies [5, 6, 10, 11, 12], was used. Microwave exposure conditions were the same for all subjects.

The 450 MHz microwave radiation was generated by the Rhode & Swartz (Germany) signal generator model SML02. The RF signal was 100% amplitude modulated by the pulse modulator SML-B3 at 40 or 70 Hz frequency (duty cycle 50%). The generator signal was amplified by the Dage Corporation (USA) power amplifier model MSD-2597601. Located in the laboratory, the generator and amplifier were carefully shielded. The 1 W EMF output power was guided by a coaxial lead to the 13 cm rod antenna NMT450 RA3206 by Allgon Mobile Communication AB, Sweden, located 10 cm from the subject's skin on the left side of the head.

The calculation of the specific absorption rate (SAR) inside the brain was based on the known field power density on skin. The Central Physical Laboratory of the Estonian Health Protection Inspection measured the spatial distribution of the microwave power density by the Fieldmeter C.A 43 Chauvin Arnoux (France) field strength meter. The calibration curves of the field power density dependence on the distance from the radiating antenna were obtained from these measurements taken in the actual conditions of the experiment. During the experiments, the stability of the microwave level was monitored by the IC Engineering (USA) Digi Field C field strength meter.

Estimated from the measured calibration curves, the field power density at the skin was 0.16 mW/cm². The level of power density was so low that thermal effects were extremely unlikely.

Recording protocols and equipment

The study consisted of three experimental protocols, identical for all subjects. The first protocol was recorded as described below.

First, the reference EEG was recorded over 60 s.

Secondly, modulated microwave radiation was applied. The duration of the exposure was 60 s, and the compensatory pause after the exposure was 60 s. Continuous EEG recordings were made during and 60 s after exposure. The procedure of the cycle was repeated ten times. The microwave exposure was switched on every first 60 s of the cycle. During ten cycles of microwave exposure, the modulation frequency always remained at 40 Hz.

The recording protocol for one subject lasted for 21 min, during which the EEG was continuously recorded.

The second protocol included the same steps, except that the modulation frequency was 70 Hz and the third protocol for the sham-exposure included also the same steps, except that the microwave generator was switched off.

The Cadwell Easy II EEG measurement equipment was used for the EEG recordings. The EEG was recorded by means of 19 electrodes, placed on the subject's head according to the international 10-20-electrode position classification system, with Cz as reference. The EEG recordings were stored on a computer at a sampling frequency of 400 Hz. The recorded EEG signals were examined by an experienced neurologist. Artifacts were detected by visual inspection. The recordings containing multiple artifacts were removed, and the whole recording was repeated.

The pre-processing of the signals was performed in the LabVIEW programming and signal-processing environment. The EEG spectrum 0.5 - 39 Hz was selected for the analysis. The results of the preceding validation of the set-up confirmed the absence of modulation components, caused by parasitic interference between EEG and radio frequency equipment.

Analysis of the EEG based on the LDLVP method

Initially, all the EEG recordings were divided into two sub-signals. The recordings performed with the first and second recording protocol were divided as follows:

- the first subsignal contained all 1 min periods without microwave exposure (all the odd minutes from the initial EEG recording),
- the second subsignal contained all minutes with microwave exposure (all even minutes of the initial EEG recording).

The recordings performed with the sham recording protocol were divided similarly:

- the first sham subsignal contained all the odd minutes,

INDIVIDUAL CHANGES IN HUMAN EEG CAUSED BY MODULATED 450 MHz MICROWAVE

the second sham subsignal contained all the even minutes of the initial recording.

The scaling analysis utilizing LDLVP method was applied for two sub-signals.

The LDLVP method has been used and described in details in our previous studies [12 – 14]. Here we provide a brief summary of this method.

First, we define the local variability as the deviation of the current value of the signal from the local average

$$\delta V(t) = V(t) - T^{-1} \int_{-T/2}^{T/2} V(t + \tau) d\tau, \quad (1)$$

where $V(t)$ is the recorded voltage, and the time-window width T is a free (adjustable) parameter. For EEG signals, a reasonable value is provided by $T = 60$ ms [14].

Secondly, low-variability periods are defined as continuous intervals with

$$\delta V(t) < \delta_0. \quad (2)$$

Finally, the number of low-variability periods N exceeding length T_0 is plotted against length T_0 , see Figure 1.

The value of δ_0 was adjusted for each recording individually, reaching a minimum value so that, for both subsignals, the length of the longest low-variability period was at least 3750 ms.

The hypothesis of this work was that microwave exposure increases EEG variability. Owing to higher variability, there are fewer long low-variability periods. Therefore it is expected that microwave exposure decreases the area of the $T_0(N)$ -curve (see Fig 1), due to faster cut-off at large values of T_0 . According to this assumption, the weighted area

$$S_w = \sum_{N=1}^{128} \ln \left(\frac{N}{\max(N-1, 1/4)} \right) \ln(T_0) N^{1/2} \quad (3)$$

of the function $T_0 = T_0(N)$ was selected as the non-linear quantitative measure.

Analysis of the EEG based on the S-parameter method

Relative changes in the EEG energy between segments with and without exposure S-parameter was selected as a measure for detection of the effect on signal intensity.

The analysis method was applied in our previous study [10], except for different comparison intervals. The energies of the different EEG rhythms were analyzed separately. Average energies for segments with and without stimulation were compared. The first 30 s of a 60 s recording segments with and without stimulation were selected as intervals for comparison. The average energy of an arbitrary comparison interval was calculated for the recording segment as follows:

$$s_i = \frac{1}{N} \sum_{r=1}^N [x(r)]^2 \quad (4)$$

where x is the amplitude of the recorded signal and N is the number of samples, during 30 seconds $N = 12000$. The relative change in the energy of the recording segments with and without stimulation was selected for further analysis. Finally, parameter S was calculated as follows:

$$S = \left(\frac{s_2}{s_1} - 1 \right) \times 100\% \quad (5)$$

where s_1 and s_2 were the average energies inside the comparison intervals without and with stimulation respectively. For sham recordings the same parameter was calculated for comparison intervals as even and odd minutes of the recordings.

At first, the energies of the four basic EEG rhythm frequencies, theta (4 – 7 Hz), alpha (8 – 13 Hz), beta1 (15 – 20 Hz) and beta2 (22 – 38 Hz), were extracted from the total EEG signal (0.5 – 48 Hz) by filtering. The parameter S was calculated separately for the EEG energies of the theta, alpha, beta1 and beta2 rhythms.

Signal processing and calculation of parameters were performed in the LabVIEW programming and signal processing environment.

Statistical analysis

For sham recordings, sub-signals were completely equivalent. The mathematical expectation of the difference in their spectral powers is zero, $\langle \tilde{W}_0 - \tilde{W}_1 \rangle = 0$. Next, an estimate of the variance could be obtained as the mean of squared differences:

$$\sigma_f^2 = \frac{1}{15} \sum_{n=1}^{15} (\tilde{W}_{0nf} - \tilde{W}_{1nf})^2 \quad (6)$$

According to the “zero hypothesis”, the EEG recordings of subjects under microwave exposure cannot be distinguished from sham signals. Thus, the “zero hypothesis” implies that $\langle W_0 - W_1 \rangle = 0$ and $\langle (W_0 - W_1)^2 \rangle = \langle (\tilde{W}_0 - \tilde{W}_1)^2 \rangle$. Consequently, if the zero hypothesis is true, the quantity

$x_f = (W_{0nf} - W_{1nf})^2 \sigma_f^{-2}$ is an f -distributed random quantity, the cumulative distribution of which is routinely designated as $F_{1,15}(x_f)$; the indices 1 and 15 stand for the numbers of the degrees of freedom.

Accordingly, the ratio of the computed power difference to the standard deviation of the differences can be used as a quantitative measure, showing how well the zero hypothesis is satisfied; respective p -values are obtained by means of the cumulative f -distribution:

$$p_f = F_{1,15}[(W_{0nf} - W_{1nf})^2 \sigma_f^{-2}] \quad (7)$$

The same technique has been applied to the non-linear quantitative measure (derived from LDLVP), resulting in another two series of p -values for recordings at modulation frequency 40 Hz and 70 Hz.

For post hoc analysis the modified Bonferroni correction was applied according to which the smallest p -value is to be multiplied by the number of data points 15, the second smallest is to be multiplied by $15/2=7.5$ etc.

Results

The results of LDLVP analysis for a subject are presented in Figure 1. The number of low-variability periods N exceeding the length T_0 is plotted versus the length T_0 for the first and second sub-signal for exposed recording. As can be seen, microwave exposure lowers the curve at the right-hand part of the graph (large values of T_0). Such a change in curve indicates that microwave exposure increases variability of the EEG signal: owing to higher variability there are fewer long low variability periods.

Figure 1. The number of low-variability periods N exceeding the length T_0 for a significant subject: black line (a) – second sub-signal of exposed recording (intervals with microwave); grey line (b) – first sub-signal of exposed recording (intervals without microwave).

INDIVIDUAL CHANGES IN HUMAN EEG CAUSED BY MODULATED 450 MHz MICROWAVE

The results of statistical analysis of the LDLVP quantitative measures for sham and microwave-exposed at modulation frequency 40 and 70 Hz recordings, calculated for each subject, are presented in Table 1. For sham recordings there were no significant results. The ratio of the computed power difference to the standard deviation of differences \sqrt{x} of more than three were considered as significant deviations from the zero hypothesis and are marked in bold. After Bonferroni correction p -values not larger than 0.05 were considered as significant deviations from the zero hypothesis and are marked in bold. As can be seen, the analysis resulted in p -values lower than 0.05 for 4 cases in the case of microwave exposure at modulation frequency 40 Hz and none for 70 Hz frequency.

The results of the S - parameter analysis for the whole group are presented in Figure 2. The graph illustrates the effect of microwave exposure – changes between exposed and not exposed segments of the recordings on different EEG rhythms and for sham, 40 Hz and 70 Hz modulation frequency. As can be seen, microwave exposure causes increase in energy of the EEG beta1 and beta2 rhythms.

Figure 2. The relative average changes in % (S - parameter) of the EEG rhythms total energy of the recording segments with and without microwave exposure in P - channels for the whole group.

The results of statistical analysis of the S - parameter are presented in Table 2. For sham recordings there were no significant results. Microwave exposed recordings at modulation frequency 40 Hz have 2 significant values in beta2 region.

The graphs of changes of the EEG rhythms energy for a significant subject are presented in Fig. 3. In this case increase in the EEG beta2 rhythm energy is more clearly indicated than in Fig. 2 for average changes in the whole group. Effect of 40 Hz modulated microwave is more evident than 70 Hz modulated microwave.

Figure 3. The relative changes (S – parameter in %) of the EEG rhythms total energy in P – channels for a significant subject.

Discussion

As table 1 illustrates, the LDLVP presents the best outcome at modulation frequency 40 Hz, resulting in significant results for 4 subjects. Accordingly, significant effect of exposure to the EEG signal was detected for 26.7 % of subjects. Modulation at frequency 70 Hz was not as effective as 40 Hz; however, it was distinguishable from sham signals, which did not result in any significant deviation.

Considering the direction of influence at modulation frequency 40 Hz, for two subjects under the exposure the computed LDLVP weighted area increased, and for two it decreased. For all subjects, the departure from the sham behavior is statistically reliable. This is somewhat different from what has been observed for the modulation frequency 7 Hz, when the sign of the departure was always negative (corresponding to increased variability) [12]. However, a study at modulation frequency 217 Hz resulted with the outcome, in which for half of the subjects the computed LDLVP weighted area decreased and for another half it decreased [15]. This observation gives us a hint that the physiological effect of the microwave stimulation depends on the modulation frequency (at least there is a difference between the 40, 217 Hz, and the 7 Hz frequencies).

INDIVIDUAL CHANGES IN HUMAN EEG CAUSED BY MODULATED 450 MHz MICROWAVE

The *S*-parameter measures exceeded the limit of significant deviation from zero hypothesis also at modulation frequency 40 Hz in beta2 frequency band (Table 2), providing 2 significant cases out of 15, that is 13.3 %. There were no significant results at modulation frequency 70 Hz. In an earlier study [10] it was suggested that microwave exposure causes a significant effect when the modulation frequency is higher or comparable with EEG rhythm frequency.

As with both methods, modulation at frequency 70 Hz is not as effective as at 40 Hz. Here we can see that achieved effect is probably concentrated to the lower frequencies. In our previous study with modulation inside the EEG physiological frequencies band the effect has been reported to be more evident at higher modulation frequencies [16]. Possible reason is that 40 Hz is quite close to the EEG physiological frequencies and the switching with brain oscillations more effective.

From those results it is difficult to conclude which measure, LDLVP or *S*-parameter, is more effective and whether the effect of modulation frequencies 40 and 70 Hz appear rather in intensity (*S*-parameter) or time variability (LDLVP) of the EEG signals. The results reported in our previous study with 7 Hz modulated microwave lead to the conclusion that the effect appears in time variability [12], while the next study concerning modulation frequency 217 Hz concluded that the effect is rather in intensity [15].

From Tables 1 and 2, it can be seen that the subjects having significant results overlap. On the other hand, with the LDLVP method, there are 4 significant results compared to 2 with the *S*-parameter. This indicates that microwave stimulation causes different effects for different subjects and there is a need for various methods to detect those effects.

The analysis by the LDLVP method detected the effect of exposure at modulation frequency 40 Hz for 26.7 % of subjects. For instance, the rate of multiple chemical sensitivity (MCS) occurrence is estimated to be between 2 and 10 % in the general population [17]. MCS is characterized by recurrent symptoms involving multiple organ systems and occurring in response to demonstrable exposures to multiple chemically unrelated compounds at doses far below those established to cause harmful effects. Taking this into consideration, LDLVP and *S*-parameter methods demonstrated good sensitivity detecting the effects of microwave stimulation at modulation frequency 40 Hz.

Main trend of changes caused by microwave exposure modulation frequencies was increase of the EEG energy in beta rhythm. Increased beta absolute power was also observed in alcohol-dependent subjects [18].

Conclusion

1. The modulated with 40 Hz 450 MHz microwave exposure caused statistically significant changes in the EEG time variability (26.7% of subjects) and energy variations (13.3% of subjects).
2. Main trend of changes was increase in the EEG beta rhythm energy.
3. The effect is more evident with the modulation frequency closer to the physiological EEG rhythms band.

Abstract

This paper proposes novel electric-field (E-field) meters that comprise an isotropic sleeve dipole sensor for a wideband frequency range, code selective receivers, and a GPS receiver.

The sensor achieves isotropy and a wideband frequency range with a high sensitivity level to measure the total exposure ratio from radio sources in the in-situ environment including a scattering domain and where multiple radio sources have different frequencies.

The strength of the E-field from a cellular base station varies dynamically because the transmission power varies depending on the amount of communications traffic. Therefore, for cellular operators, it is important to estimate conservatively the exposure ratio from their base stations at the designed maximum transmission power. A code selective receiver is adopted for conservative estimation of the exposure ratio from the IMT-2000 cellular base stations, which are becoming commonplace worldwide.

The proposed E-field meters can accurately assess the total exposure ratio from 30 MHz to 3 GHz and the profile of the human exposure ratio from IMT-2000 cellular base stations based on in-situ measurement. In addition, we show that the exposure ratio from a typical IMT-2000 cellular base station is less than 1/10000 of the E-field strength reference level given in the ICNIRP guidelines.

Keywords: IMT-2000 cellular system; the ICNIRP guidelines; radio receivers

1. Introduction

When starting the service of a new cellular base station, the E-field strength from the base station must be below the E-field reference level given for the country in which the base station is established. Furthermore, if there are other radio stations around the base station, the electromagnetic environment including the radio waves from the surrounding stations must be evaluated comprehensively. The reference levels for the E-field strength are different for each radio law. However, many radio laws adopt the reference levels given in the ICNIRP guidelines (the ICNIRP reference levels) [1]. The ICNIRP reference levels are different for each radio wave frequency. Therefore, if the E-field strength levels are evaluated in an environment where the radio waves from multiple radio stations have different frequencies, it is important to assess the total exposure ratio considering the difference between the E-field strength levels at each frequency.

For cellular operators, it is important not only to comply with the ICNIRP reference levels, but also to communicate to the general public to enhance public confidence and acceptability for radio frequency (RF) exposure as indicated in the fact sheet issued by the World Health Organization [2]. Therefore, an E-field meter that accurately assesses the total exposure ratio, which is the summation of the squared ratios of the E-field strengths to the ICNIRP reference levels, in the in-situ environment is required.

In order to enhance public confidence and acceptability for RF exposure, it is important to estimate not only the total exposure ratio, but also the profile of the exposure ratio from a cellular base station. The radio waves from cellular base stations include many kinds of digital modulated waves with different frequencies. In addition, the E-field strength from a cellular base station varies dynamically because the transmission power varies depending on the amount of communications traffic. In order to assess the maximum exposure ratio from a cellular base station, an assessment of the E-field strength from the base station at the maximum designed transmission power is required. Therefore, the E-field meter that accurately assesses the profile of the exposure

ratio from a cellular base station in the in-situ environment is required to be optimized to the digital modulated waves.

The objective of this paper is to specify, for such an E-field meter and when it is put into service in its operational environment, the methods to assess the value of the total exposure ratio in relevant public-access areas in order to communicate the risk to the general public.

This paper proposes the following two E-field meters.

- a) An E-field meter for assessing the total exposure ratio.
- b) An E-field meter for assessing the profile of exposure ratio from a cellular base station.

In particular concerning b), the E-field meter for the IMT-2000 cellular system, which is the 3rd generation cellular system and is becoming commonplace worldwide, is proposed.

2. Basic Configuration

a) E-field meter for assessing the total exposure ratio

In order to conform to the ICNIRP reference levels, the total exposure ratio should be less than or equal to one. The total exposure ratio is estimated using (1),

$$e_t^2 = \sum_{i=100\text{ kHz}}^{1\text{ MHz}} \left(\frac{E_i}{c} \right)^2 + \sum_{i>1\text{ MHz}}^{300\text{ GHz}} \left(\frac{E_i}{E_{L,i}} \right)^2, \quad (1)$$

where e_t^2 is the total exposure ratio, E_i V/m is the E-field strength at frequency i , and c and $E_{L,i}$ V/m are the ICNIRP reference levels at frequency i .

An E-field meter that measures the strength of the E-fields including those from cellular base stations, FM radio stations, and TV stations, must have a high level of sensitivity throughout a wideband frequency range. In the construction of a wideband E-field sensor, a shorted-dipole element that is shorter than the wavelength is often combined with a diode detector. The detection sensitivity limit of this sensor is approximately 0.1 V/m (100 dB μ V/m). However, in order to measure the strength of the E-fields around a cellular base station in the in-situ environment for practical purposes, the detection sensitivity of the E-field sensor must be 1 mV/m (60 dB μ V/m).

In addition, in order to measure the E-field strength accurately, the sensor polarization must be set to conform to the target electromagnetic wave polarization. However, in the in-situ environment in which the equipment is surrounded by many reflectors, which is representative of many urban areas, accurate measurement is difficult due to the presence of the scattering domain in the case of measurement using the E-field sensor comprising a shorted dipole. On the other hand, the isotropic E-field sensor enables measurement of the E-field strength without depending on the polarization of the target wave. Therefore, in an in-situ measurement the isotropic E-field sensor must be used.

The target measuring frequency range of the proposed E-field meter is assumed to be from 30 MHz to 3 GHz, which includes the frequencies used by cellular services and many other wireless services. When measuring the strength of the E-field from a cellular base station, as mentioned above, it is practical to have the detection level of 60 dB μ V/m. In order to satisfy this requirement, the construction of the proposed E-field sensor is based on a frequency tuning measurement instrument for detection. The relationship between the required sensitivity and antenna factor (AF) for the E-field sensor is given as (2),

$$E_{REQ} = n + SNR + AF_{REQ} + 107, \quad (2)$$

where E_{REQ} dB μ V/m is the required sensitivity level, AF_{REQ} dB/m is the required AF, n dBm is the noise floor of the instrument, and SNR dB is the signal-to-noise ratio (SNR).

If a general spectrum analyzer with the noise floor of -90 dBm for the resolution bandwidth of 100 kHz is adopted as the frequency tuning measurement instrument, in order to achieve the sensitivity of 60 dB μ V/m, the AF of 40 dB/m is required for the E-field sensor. In this regard, it is assumed that the E-field sensor can detect the E-field strength, if the SNR is greater than 3 dB.

In order to achieve sensor elements and baluns that exhibit a high sensitivity level across a wideband frequency range, the sensor element design is based on a sleeve dipole and divided sub-elements that correspond to each frequency range. The proposed sensor element comprises a radiator, a sleeve, and a coaxial feeder as shown in Fig. 1.

The radiator comprises multiple cylindrical conductors connected by inductors. The lengths of each conductor are based on a log periodic rule. The inductors function to change the effective length of the radiant region for each frequency because the impedance of the inductors increases with an increase in the frequency. The sleeve is also basically constructed in the same manner as the radiator. However, in the sleeve region, the

ELECTRIC-FIELD METERS FOR ASSESSING THE EXPOSURE RATIO FROM MULTIPLE RADIO SOURCES AND IMT-2000 CELLULAR BASE STATIONS

Fig. 1. Construction of proposed sensor element for assessing the total exposure ratio

a spectrum analyzer, and a notebook PC to control the switch box and spectrum analyzer. A schematic and a photo of the equipment are given in Figs. 2 and 3, respectively.

The spectrum analyzer detects the signal induced at an axis of the proposed E-field sensor. The E-field strength detected by the axis of the proposed sensor is calculated using (3),

$$E_x = P_x + AF_x + L_x + 107, \quad (3)$$

where E_x dBμV/m is the E-field strength detected at the x axis, P_x dBm is the received power for the x axis detected by the spectrum analyzer, AF_x dB/m is the AF of the x axis, and L_x dB is the cable loss between the x axis of the sensor and the spectrum analyzer. E_y and E_z are the same as E_x .

The E-field strength of a point of interest is calculated using (4),

$$E = \sqrt{E_x^2 + E_y^2 + E_z^2}, \quad (4)$$

where E μV/m is the root mean square of E-field strength of E_x , E_y , and E_z .

The switch box selects the connection to an axis element of the proposed sensor and the spectrum analyzer. The notebook PC controls the switch box and spectrum analyzer, calculates the total exposure ratio using (3), (4), and (1), and shows the frequency spectrum with the ICNIRP reference level and the total exposure ratio.

b) E-field meter for assessing the exposure ratio profile from a IMT-2000 system base station

In order to assess the strength of the E-field from a cellular base station at the maximum designed transmission power, it is effective to utilize characteristics of the transmission power allocated to the control channel. These characteristics are that the transmission power is constant at each cellular base station and that the power is independent of the amount of communications traffic.

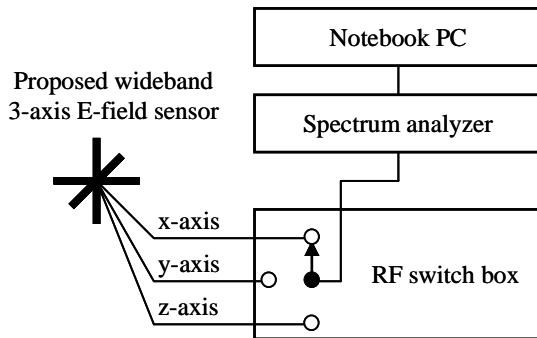

Fig. 2. Construction of proposed E-field meter for assessing the total exposure ratio

coaxial feeder is at the center of the conductors, and ferrite elements are inserted between the feeder and the conductors. These ferrite elements provide a sufficient degree of isolation between the feeder and the conductors of the sleeve.

The length of the proposed sensor element including the radiator and sleeve regions is 600 mm, the diameter of the outside conductors is 9 mm, and the entire sensor element is covered with fiber-reinforced plastic (FRP).

Isotropic sensitivity is required for the E-field sensor in the in-situ measurement as mentioned above. Therefore, the proposed E-field sensor comprises three sensor elements that cross orthogonally in a three-dimensional Cartesian coordinate system for the isotropic sensitivity.

The proposed E-field meter integrates the proposed wideband 3-axis isotropic E-field sensor above, a switch box for RF signals,

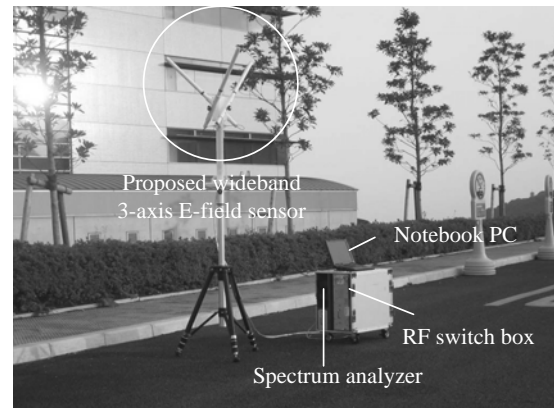

Fig. 3. Proposed E-field meter for assessing the total exposure ratio

The relationship between the total exposure ratio and the exposure ratio from a cellular base station at the designed maximum transmission power is given as (5),

$$e_t^2 = e_{EUT}^2 + e_x^2, \quad (5)$$

where e_t^2 is the total exposure ratio, e_{EUT}^2 is the exposure ratio from a cellular base station at the designed maximum transmission power, and e_x^2 is the exposure ratio from other radio sources.

In the 2nd generation cellular systems, since the access system is based on the frequency division multiple access (FDMA) system, the strength of the control channel E-field can be adequately measured at the frequency range assigned to the control channel by frequency tuning using a spectrum analyzer. On the other hand, the 3rd generation cellular systems are based on the code division multiple access (CDMA) system. In this system, the frequency spectra of the communication channels overlap. Therefore, in order to measure the E-field strength of the control channel in the wideband code division multiple access (W-CDMA) system, code selective receivers are required. The control channel is called the primary common pilot channel (P-CPICH) in the 3GPP specification [3].

The exposure ratio from W-CDMA system base stations is given as (6) and (7),

$$e_{EUT}^2 = \sum_{i=1}^{N_{EUT}} \left(\frac{E_{rec,i}}{E_{L,i}} \right)^2, \quad (6)$$

$$E_{rec,i}^2 = N_{code} \times E_{P-CPICH}^2, \quad (7)$$

where e_{EUT}^2 is the exposure ratio from a cellular base station at the designed maximum transmission power, N_{EUT} is the number of radio sources at the W-CDMA system base station, $E_{rec,i}$ is the received E-field strength due to i -th radio source at W-CDMA system base station, $E_{L,i}$ is the ICNIRP reference level at the i -th radio frequency, N_{code} is the number of traffic codes, and $E_{P-CPICH}$ is the E-field strength of the P-CPICH code.

The proposed E-field meter integrates an isotropic E-field sensor comprising the 3-axis dipole elements used in the in-situ measurement, three code selective receivers to detect the W-CDMA system signals, a GPS receiver to detect the geometrical position, and a notebook PC to control the receivers. A schematic and a photo of the equipment are given in Figs. 4 and 5, respectively.

The E-field sensor comprises the 3-axis mutually-perpendicular dipole elements because isotropic sensitivity is required for the E-field sensor in the in-situ measurement as described above. The three code selective receivers correspond to each axis of the isotropic sensor, and detect only the P-CPICH intensity.

The notebook PC controls the code selective receivers and calculates the exposure ratio from the target base station at the designed maximum transmission power. The P-CPICH E-field strength of an interesting point is calculated using (3), (4), and (7). The exposure ratio from a base station at the designed maximum power is calculated using (6). Furthermore, this equation obtains the geometrical position information from the GPS receiver and shows the geometrical profile of the exposure ratio from the target base station.

Table 1. Code Selective Receiver Characteristics for Exposure Ratio from IMT-2000 System Base Station

Item	Value
Frequency Range	2110~2200 MHz
Dynamic Range	-117~-33 dBm
Resolution	0.1 dB
Accuracy	± 2 dB
SIR Accuracy	± 3 dB
Sampling Interval	10 ms

3. Characteristics

a) E-field meter for assessing the total exposure ratio

The AF frequency characteristics of the proposed E-field sensor are shown in Fig. 6. The AF is calibrated by using a standard antenna.

The E-field sensor achieves an AF value of 40 dB/m from 30 MHz to 1.7 GHz, and 41 dB/m from 1.7 GHz to 3 GHz.

The isotropic response of the proposed sensor is measured using an SG system (Satimo S. A.). The measurement values at 2 GHz, which is used by W-CDMA systems, are shown in Fig. 7.

Figure 7 shows that the isotropic response of the proposed sensor is within ± 5 dB except for below the proposed sensor where there is a tripod stand.

b) E-field meter for assessing the exposure ratio profile from a IMT-2000 system base station

The characteristics of the code selective meter are given in Table 1. For example, at 2 GHz, the AF value of the isotropic sensor in the proposed E-field meter is 45.2 dB/m. Therefore, the proposed E-field meter is estimated to achieve the sensitivity of 0.06 mV/m using (2).

4. Measurement example

a) E-field meter for assessing the total exposure ratio

The total exposure is measured using the proposed E-field meter in an urban area and is shown in Fig. 8.

Figure 8 shows that the proposed E-field meter can assess the exposure ratios from not only cellular base stations, but also other stations such as TV stations. In addition, it shows that the total exposure ratio is approximately 1/5000 (2.08e-2%), and is sufficiently lower than the ICNIRP reference level.

b) E-field meter for assessing the exposure ratio profile from a IMT-2000 system base station

The exposure ratio from a W-CDMA system base station is assessed using the proposed E-field meter. The base station antenna is located in a rural area. The total exposure ratio is assessed approximately every 50 cm from under the antenna to approximately 1.6 km away. The height of the upper end of the antenna attached to a mast is 39.7 m. The total transmission power is 48 W per radio sector. The ICNIRP reference level for the 2-GHz band indicated in the ICNIRP guidelines is 61.4 V/m [1]. The assessed profile for the total exposure ratio is shown in Fig. 9. The figure shows that the maximum value of the total exposure ratio from this base station is approximately 1/10000 of the ICNIRP reference level.

Fig. 7. Isotropic responses of the proposed E-field sensor for assessing the total exposure ratio

Fig. 8. Measurement example using proposed E-field meter for assessing the total exposure ratio

Fig. 9. Measurement example using proposed E-field meter for assessing the exposure ratio from IMT-2000 system base station

5. Summary

The proposed E-field meters achieved the following points.

- 1) The sensitivity of 1 mV/m was achieved using only one E-field sensor in the frequency range from 30 MHz to 3 GHz, and the total exposure ratio from multiple radio stations was assessed in the frequency range.
- 2) The E-field meter for assessing the exposure ratio profile from an IMT-2000 system base station comprises code selective receivers was presented, and the exposure ratio profile was assessed.
- 3) The total exposure ratio is less than 1/5000 of the ICNIRP reference level in an urban area.
- 4) The maximum value of the exposure ratio profile from a W-CDMA base station is less than 1/10000 of the ICNIRP reference level in a rural area.

ABSTRACT

In this work we investigated the effect of the human operator body on the measurement of an electric field with a broadband probe. The finite-difference in time-domain technique was used to evaluate the influence. A numerical model of a commercially available probe was created and examined for its operation both within and outside its intended frequency use. Two homogeneous models of the human operator made of dispersive muscle-like material were considered. The first one was with the arm raised above the head at an angle of 45° with the horizon and the second one was with the arm extended in front of the thorax. Several angles of incidence of the plane wave were simulated and it was shown that the former configuration (arm raised) resulted in more accurate measurements than the latter one. Furthermore, it was established that not only the presence of the human was responsible for the discrepancy of the measured values, but also the input impedance of the probe's dipoles which changed, due to coupling with the human body, thus altering the antenna factor that had been calculated during calibration.

I. INTRODUCTION

In the recent years, the concern, which arose about the possible health hazards of non-ionizing electromagnetic radiation, has led to the introduction of standards or safety guidelines on exposure. In order to compare with the limiting values set in such documents, it is necessary to have a probe that can accurately measure the electric field. There are a lot of factors, which reduce measurement accuracy. The most typical and frequent factors result mainly from the type of antenna used inside the probe, its size, and the mutual coupling between the antenna and the radiation source. Apart from the above, other factors include the detector's dynamic characteristics, the termination of the measurement probe and the deformation of the measured field, which is caused, e.g. by the person performing the measurement.

In the present study, we examine the influence of the human operator on the calibrated characteristics of a field probe and, consequently, on the measurement accuracy. In particular, we investigate what is the effect of the proximity of the human body on the probe's frequency response, its isotropicity and the calculated antenna factor (AF).

II. MATERIALS AND METHODS

Principle of operation of a broadband probe

A broadband probe of the electric field usually consists of a dipole antenna, a non-linear detector, lumped elements, which are used for filtering and shaping, a transmission line and some monitoring instrumentation. The principle of operation of the probe is based on the production of a voltage across the detector at the antenna terminals, when a continuous wave field is applied. This radiofrequency voltage has a dc component proportional to the square of the incident field, due to the non-linear characteristics of the detector. This component is filtered and is conveyed over the transmission line to the monitoring instrumentation. In order to obtain an omnidirectional pattern of the measurement probe, it is necessary to use three mutually perpendicular antennas and to sum their output voltages, so as to result to the output voltage [1].

Numerical model of the broadband probe

The numerical modeling was performed with the use of the finite-difference in time-domain (FDTD) technique. The model of the probe was based on a real product (Narda Model 8760), which operates in the frequency range from 300kHz to 1GHz. The isotropicity of the probe was achieved with three dipoles, which were placed on planar substrates combined to form a beam with the cross section of an equilateral triangle. Each of the orthogonal dipoles formed an angle of 54.74° with the axis of the beam (Figure 1). These dipoles consisted of a

layer of a perfect electrical conductor with 9cm length, 4cm width and 0.2 mm thickness, printed on a dielectric substrate 1.4mm thick, of which the dielectric constant was assumed to be 3. Across the gap between the two parts of the dipole antenna a lumped element was mounted with resistance $1M\Omega$, where the induced voltage was measured due to the incident electric field (linear detector). The effective voltage of the measurement probe resulted from the summation of the induced voltages of the three dipoles, after squaring them. This structure was placed inside an empty cup, whose shape was conical. The shaft of the probe was assumed made of dielectric material, with the same dielectric constant 3, and had a radius of 2cm.

Figure 1: (a) Cross section of the probe (b) Side view of the probe with the dipoles

During the process of calibration, the probe was excited by a plane wave with vertical polarization and field strength of 1V/m. Figure 2 presents the frequency response of the probe in the frequency range from 300kHz to 2.4GHz. The response in the operation range of the probe was almost frequency independent and its flatness was within $\pm 0.75\text{dB}$. When the frequency was increased beyond the point where the dipole antenna is electrically short ($\beta_0 h < 0.3$), the response was seen to peak in the vicinity of the frequency for the first resonance of the dipole antenna ($\beta_0 h = \pi/2$), which is approximately at 1.6GHz. The curves of Figure 3 indicate that the probe's linearity is very weakly dependent on the frequency in its operation range. The radiation pattern of the probe (not shown here) confirms that isotropy is achieved by the mutually orthogonal configuration of the three dipoles.

Figure 2. Frequency response of the numerical model of the probe to a plane wave of vertical polarization and electric field strength of 1V/m

Figure 3. Response of the numerical model of the probe to a plane wave of vertical polarization and varying electric field strength for several frequencies

Through the process of calibration the antenna factor (AF) in dB(1/m) can be determined:

$$AF = 20 \log_{10} \left(\frac{E}{V} \right) \quad (1)$$

where E is the electric field incident on the antenna and V is the voltage developed across the output of the antenna. Accordingly, an unknown electric field can be determined by the calibrated probe in terms of the measured voltage. Figure 4 shows the calculated AF, which seems to be approximately flat in the operation range, while the range of the first resonance of the dipoles is obvious.

Figure 4. The antenna factor (AF) of a probe calibrated with a plane wave of vertical polarization

Numerical model of the human operator

Our computations assumed a human model of 1.70m height, 0.4625 width and 0.47m depth, which was available on the internet (www.3dcafe.com). The hand of the model was moved with program CtrlView® (www.ctrlview.com) to create two different human models. Figure 5a shows the human model for which the direction of the hand forms a 45° angle with the horizon. For the second model the direction of the hand coincided with the direction of the horizon (Figure 5b). Both models were homogenous and consisted of material corresponding to human muscle. The dielectric properties of the muscle-simulating material were described by a 2nd order Debye model, in order to take into account the frequency dependency of them in the range of 300kHz to 2.4GHz. The constants assumed were $\epsilon_{\infty}=40$, $\epsilon_{s1}=3948$, $\epsilon_{s2}=59.09$, $\tau_1=4.62 \times 10^{-8}$ s, and $\tau_2=9.11 \times 10^{-10}$ s.

Figure 5: (a) Human model with raised arm (b) Human model with extended arm

III. RESULTS

In the following we discuss the influence of the human body on the frequency response and the isotropicity of the calibrated probe. Figure 6 presents the frequency response of the probe, when the latter was used by the first and second human model respectively and was illuminated by a plane wave similar to that used in the calibration procedure. In both cases the variation with frequency was more intense than when the probe was in free space, a fact which confirms that the presence of the human affects the electromagnetic environment. In the case of the second model (Figure 6b), the influence of the human was more evident, because the measurement was performed in front of the body, which results in the probe being influenced by all the changes of the field caused by the human. In both models alterations were also observed in the isotropicity of the measurement probe, especially in the vertical plane. The second model seems to have affected more the isotropicity of the probe than the first one and especially in the higher frequencies, where the wavelengths became smaller than the model's dimensions.

Figure 6: Calibration response of the probe in the presence of the human model (a) and (b) of Figure 5.

In the present study we also investigated a series of measurement configurations, in which the probe was held by the human model and was excited by plane waves with different polarizations and from different directions. Initially we simulated the first human model (raised arm) with the probe for a vertically polarized incident plane wave coming from the front of the model. With regard to the accuracy of the measurement, we always compute the percent relative divergence of the measured and the actual field based on:

$$J[\%] = \frac{E_{TRUE} - E_{MEASURED}}{E_{TRUE}} \times 100 \quad (2)$$

Figure 7 demonstrates the deviation as a function of the frequency of the incident wave. It seems that the measured field followed to a satisfactory degree the variations of the actual field in the probe's operation range (300kHz - 1GHz), where the deviation was less than 1.6dB. This divergence of field was caused by the changes of the dipole's input impedance, because of the coupling, which takes place between the human model and the measurement probe. This variation of impedance of the three dipoles is shown in Figure 8, where it can be noticed that there fluctuations in the lower frequencies and a stabilization in the range above 200MHz.

Figure 7. Deviation of the measured electric field from the true electric field for the human model with the raised arm

Figure 8. Deviation of the input impedance of the probe's dipoles due to coupling with the human body

In the higher frequency range (above 1 GHz) the difference between the measured and the actual field was greater than in the operation range, not only due to the change of the impedance of the dipoles, but also because of the reduction in the calculated AF, since this is the range of dipole resonance. As a result there was an underestimation of the electric field up to 55%. This means that when the probe is used in an environment of multiple sources, there must be adequate filtering, so that the measurement is not contaminated by fields in the frequency range, where the probe fails to operate correctly.

As a further step, we examined the incidence of the plane wave from various other angles and not only from the front of the model. The different deviation between measured and actual field established that the coupling between human and probe was dependent on the direction of the incident field. Moreover, we simulated a horizontally polarized plane wave irradiating the human operator from the front, showing that coupling also depended on field polarization.

We repeated the above procedure for the second human model (extended arm). Figure 9 shows that this model affected more the accuracy of measurement than the first one, when it was illuminated from the front, because of the fields scattered by the human body. In this case, the deviation of the measured value from the true one reached 4dB. However, for the higher frequencies ($> 100\text{MHz}$), this deviation became less than 2dB, when the field was incident from the back of the human operator.

Figure 9. Deviation of the measured electric field from the true electric field for the human model with the extended arm

IV. DISCUSSION - CONCLUSIONS

The use of a probe consisting of three mutually vertical dipoles can be used for the measurement of electric fields only in its operation range. The frequency response of the probe is limited by the dipoles dimensions. The cup or the shaft of the probe do not seem to affect the measurement, as long as they are present in its calibration. However, the presence of the human operator changes the incident electromagnetic field. As a result the probe does not measure the real incident field, but the one developed around the human operator. The deviation is larger when the operator holds the probe with an extended arm in front of him/her and becomes smaller when he/she holds it with an arm raised above his/her head at an angle of 45° with the horizon. This is actually the way of use proposed by the manufacturer and has been confirmed by the simulations conducted in this study. For this configuration, it was found also (not presented here) that the effect of the ground is minimized, since the probe is high above it.

Another source of inaccuracy in the measurement is the change of input impedance of the dipoles, since they couple with the dielectric body of the human operator. This change in impedance leads to a different AF from the one evaluated during the calibration. Therefore, even if the incident field remained unchanged, the probe would still give a wrong field value. The coupling of the probe with the human body depends on the angle of arrival, the frequency and the polarization of the incident field, making the introduction of a correction factor impossible.

Abstract

GSM DCS 1800 mobile phone radiation emitted by Nokia 3210 (0.81 W/kg digital SAR) was measured by electromagnetic radiation meter while speaking into phone by different frequency-strength pure tone and human voices generated sound production device, also in quiet condition in the sound-proof room. The measurements are taken in 2-second-periods as instantaneously during 6 minutes and saved in high configuration computer. Average values of these measurement data were calculated after whole experiment concluded.

In quiet condition, 7.7 V/m external E fields were averaged. Applied pure tone, man and woman voices, between 0-120 dB strength and 125-8000 Hz frequency range made E field values increase approximately as 24 V/m.

It was detected that all types of sound in 60 dB strength and having 3-4 kHz frequencies, daily life speech range are the threshold for mobile phone radiation increment. Statistically insignificant change was observed between quiet condition and below 60 dB range. 60 dB and loader voices in the range of 1-4 kHz frequencies generated nearly the same E field values as 24 V/m.

Introduction

Number of mobile phone users already above 2 billion and it is anticipated that this number will reach to 5 billion next 5 years. Not only basic qualifications such as voice, data and image transfer, but also mobile phones becoming multi terminal devices make the body of consumer grow. Innovations on mobile phone technology are actualized everyday such as models taking picture, recording video, for babies and having options of “push and talk” which teenagers like and use very often. The wide and growing use of cellular phones has also raised questions about the possible health risks associated with Radio Frequency (RF) electromagnetic fields. In order to estimate health risks, cellular phone users have to obtain the relative exposure levels. However, the RF exposure level is very difficult to measure accurately and quantify for all individuals as SAR (Specific Absorption Rate) because exact measurements of SAR in vivo, which has a direct effect on user in relation to the output level of cellular phone, are almost impossible¹. ICNIRP (International Commission for Non-Ionizing Radiation Protection) prepared guidelines for limiting EMF exposure directly related to adverse health effects caused by EMF radiation by means of coupling with body directly or indirectly. Two classes of guidance are presented as Basic restrictions and Reference levels. Basic restrictions are the restrictions on exposure to time-varying electric, magnetic, and electromagnetic fields that are based directly on established health effects. Depending upon the frequency of the field, the physical quantities used to specify these restrictions are current density (**J**), specific energy absorption rate (SAR), and power density (**S**). Reference levels are provided for practical exposure assessment purposes to determine whether the basic restrictions are likely to be exceeded. Some reference levels are derived from relevant basic restrictions using measurement and/or computational techniques, and some address perception and adverse indirect effects of exposure to EMF. The derived quantities are electric field strength (**E**), magnetic field strength (**H**), magnetic flux density (**B**), power density (**S**), and currents flowing through the limbs (**IL**)^{2,3}. In other words, determining of the reference levels gives information about if the basic restrictions are exceeded.

In this study, we measure the cellular phone radiation operating in GSM DCS 1800 MHz by using electromagnetic radiation meter in order to determine the individuals' exposure levels to inform the quantity of exposure and estimate health risks. Mobile phone, Nokia 3210 with 0,81 W/kg digital SAR value was used.

Measurements were executed while pure silence, and also applying pure tone, man and woman voices, between 0-120 dB strength and 125-8000 Hz frequency range spoken into the mobile phone in a pure silent room.

Materials and Methods

Two identical Nokia 3210 (0.81 W/kg) were chosen as mobile phones for which we obtain the exposure level while speaking into the phone with the human voices in different frequencies and intensities. Also we measured the exposure value when pure tone applied. Pure tone, artificial sound not exist in nature, was generated by audiometer (Interacoustics Clinical Audiometer AC 40) applied to mobile phone microphone as receiver using headphone (SONY). Audiometer operates pure tone in 0-120 dB strength and 125-8000 Hz frequency range. Also, it can modulate average tone of man and woman voices into different frequencies and strengths in the same range. A woman and a man volunteers whose voices are in the average range of frequencies. NARDA EMR 300 and type 8.3 probe were used as radiation measurement device. Measurements were taken for duration of 10 minutes per 2 seconds and the data saved to the computer connected to device via fiber optic cable. The whole data were averaged before statistical analysis.

4 cases as “pure silence”, “pure tone”, “woman voice”, “man voice” are analyzed if measured external E field levels change with respect to type, frequency and intensity of voice.

Result

For Nokia 3210, there is an increase for certain frequencies and strengths in tree of these four cases of which “pure tone”, “woman voice”, “man voice” with respect to “pure silence”(p<0.05). However, this increase is independent of voice type, namely external E field levels are the same for “pure tone”, “woman voice”, “man voice”.

For 125 Hz, E field is 7,68 V/m same as in pure silence mode in all intensities starting from 0 dB up to 120 dB. For 250 Hz, with the voice of 90 dB, 100 dB and 110 dB intensities speaking into mobile phone changing the external E field level as 23,89 V/m ; 24,26 V/m ; 24,19 V/m respectively. For 500 Hz; changes in E field beginning between of 90 dB and 120 dB the intensities as 24,13 V/m by 90 dB; 24,26 V/m by 100 dB; 24,17 V/m by 110 dB and 24,17 V/m by 120 dB. For 750 Hz; voices between 80 dB-120 dB intensities makes field values as 24,1 V/m; 23,83 V/m; 24,25 V/m; 24,16 V/m and 24,15 V/m respectively. Also, the E field level changed by applying the voice intensity of the same range for 1 kHz as 24,15 V/m; 23,87 V/m; 24,23 V/m; 24,18 V/m and 24,15 V/m . The threshold intensity that change the E field level generated by mobile phone for 1.5 kHz sound is 70 dB. The E field levels for intensities between 70 dB and 120 dB are 24,13 V/m; 24, 13 V/m; 23,9 V/m; 24,18 V/m; 24,15 V/m respectively. Again for voice having 2 kHz frequency and intensities changing from 70 dB to 120 dB, the field values are 24,13 V/m; 24,13 V/m; 24,07 V/m; 24,23 V/m; 24,16 V/m and 24,16 V/m.

Voice in frequency of 3 kHz makes the E field value change if these voices are 60 dB and more strength. For 2 kHz and 60 dB voice makes E field level as 23,81 V/m. and for the other intensity of voices in this frequency which increase the level of mobile phone's radiation are 24,12 V/m; 24,29 V/m; 24,28 V/m; 24,25 V/m and 24,22 V/m respectively. For 4 kHz also there are the same range of intensity as 60 dB – 120 dB having E field value as 23,95 V/m; 24,13 V/m; 24,13 V/m; 24,43 V/m; 24,41 V/m and 23,73 V/m and 23,55 V/m respectively. In 6 kHz, only 110 dB and 120 dB voices increase the radiation as 24,22 V/m and 24,20 V/m. For 8 kHz voices in all strengths, E field value measured as 7,89 V/m nearly the same as in pure silence mode. Table 1 contains all these data in detail. For this reason, whole data averaged for three types of voices (Table 1, Figure 1-4)

Discussion

The use of mobile phone by adult, young people, children and the elderly has grown rapidly which causes increased concern of public, scientists and experts about the health effects of these phones in the last years. Therefore, the intensive research continues to be carried out in order to find if they cause any possible health risk for humans.

GSM-1800 signals SAR levels ranging from 0.1 to 2 W/kg. Modulations named as GSM-217, GSM-Basic, GSM-DTX or GSM-Talk have SAR values between this range.

GSM-217Hz is GSM signals are amplitude modulated by rectangular pulses with a repetition frequency of 217 Hz and a duty cycle of 1:8 (pulse width 0.576 ms), corresponding to the dominant modulation component of GSM. The ratio between slot average SAR and time average SAR is 8. GSM- Basic is in addition to this basic GSM-217Hz TDMA frame, every 26th frame is idle, which adds an 8 Hz modulation component to the signal . The ratio between slot average SAR and time average SAR is 8.3. The discontinuous transmission mode (DTX) is active during periods without speaking into the phone. To save battery power, the transmission is reduced to 12 frames per intermediate multiframe of 104 frames (compared to 100 frames for GSM Basic). The frame structure of the DTX signal results in 2, 8 and 217 Hz components. The ratio between slot average SAR and time average SAR is 69.3.

GSM-Talk generates temporal changes between GSM-Basic and GSM-DTX and simulates a conversation with an average duration of 97s and 50s for Basic and DTX, respectively. The ratio between slot average SAR and time average SAR is 11.9. Furthermore, arbitrary field on/off intermittence in the range from seconds to hours can be applied^{4,5,6}.

In this study, Mobile phone Nokia 3210, spoken into the phone, mostly in GSM Basic mode measured externally in order to obtain an opinion about how much user exposure. All in all, we found that the external E field which mobile phone generates while user speaks into phone without cease is triple of the measured value while nobody speaks into phone when conversation is ended for both user.

In Lonn at al. study, the output power for all mobile phone calls managed by GSM operator Telia Mobile was recorded during one week in four defined areas (rural, small urban, suburban and city area) in Sweden⁷. The recording included output power for 900 MHz and the 1800 MHz frequency band. Conclusion of this report is that in rural areas where base stations are sparse, the output power level used by mobile phones are on average considerably higher than in more densely populated areas. So, our experiment was done in pure silent room in the city center where the base stations near and actively operated and in the time period of before primetime (09.00-11.30 AM), prime time(12.00- 13.30 AM) and after prime (14.00-17.00 AM) time of weekdays.

As a result, we found that mobile phone user expose more RF radiation when he / she is talking in the periods out of prime time. In the period called as prime time the external E field value is constant both for silence and speaking into mobile phone.

There is no difference if the voice belonging to woman, man or child on the level of external E field that mobile phone generates. There is threshold level of sound intensity changing mobile phones technology. 50 decibels (dB) the range of whispering is the threshold strength in order to recognize the voice which is speaking into mobile phone Nokia 2100 although 60 dB can be solely threshold for Nokia 3210.

A quantitative assessment of individual exposure to radiofrequency fields epidemiological studies of possible health effects for many reasons.

Table 1: External electric field values (V/m) generated by Nokia 3210 in GSM-Talk modulation with pure tone, woman and man's voices in a sound proof room.

MAGNETIC FIELDS FOR RELIEF OF MYOFASCIAL AND/OR LOW BACK PAIN THROUGH TRIGGER POINTS

Carlton F. Hazlewood, Marko S. Markov

**Research Consultants International, Houston, USA, e-mail: carltonh@swbell.net;
Research International, Buffalo USA email: msmarkov@aol.com**

Abstract

It is known that a significant fraction of both acute and chronic pain experience is myofascial in nature. This paper address the potential for pain relief to be induced by placing magnets over the trigger points associated with that referred pain. This is even more important in patients with various disabilities and experiencing chronic sacro-iliac and/or low back pain.

It is well recognized that a trigger point is a functional, rather than an anatomical, entity. From the point of view of magnetotherapy it appears to us that the trigger points represent a plausible physiological/tissue "window" and/or pathways which allows magnetic fields to penetrate through physiological barriers and thus returning injured tissues to the homeostatic state. It should be noted that these "tissue windows" represent physiological "entrance points" for eventual exogenous stimulations, mainly physical by nature, to enter the body.

There is evidence that the application of magnetic field (via permanent magnets) on trigger points is more effective for pain relief as compared to other parts of the body surface. The systemic effects should also be considered when magnetic field effects are discussed. (We first presented this idea at the 2004 meeting in Kos.)

We discuss the mechanisms of action related to ion transport as central to the integrity and proper functioning of nerve excitability and muscle contraction. Any disruption of their normal function would directly and markedly affect human neurosensory and neuromotor performance. Biophysical phenomena associated with modification of ion transport are in the millivolt and picoampere range. Therefore, electrophysiological changes in ion channel functions are among the most sensitive indicators, if not the most sensitive indicator, to detect and quantify physiological effects of electromagnetic fields.

We postulate that in addition to the known effect of magnetic fields on water structure there could be a change in the tensile properties of cartilage, ligaments, and other soft tissue structures which secondarily may relieve tension on arthritic joints or on chronically "inflamed" areas.

Introduction

Increasing interest in alternative and complimentary medicine has attracted the attention of scientists and clinicians to the potential benefit of using various static magnetic fields and EMFs for therapeutic purposes. It is now clear that magnetic fields interact with biological tissues in a way that specific physiological changes occur. Both static and time varying magnetic fields were successfully applied to treat therapeutically resistant problems in the musculoskeletal system (Bassett, 1989 and 1994; Pilla and Markov 1994; Markov 1995; Itoh, et al., 1991; Markov and Pilla 1995; Shupak, 2003; Rosch and Markov, 2004). It is accepted that EMFs provide a practical, exogenous method for inducing cell and tissue modifications that can correct selected pathological sites. The most effective clinical applications of these physical factors are related to bone unification as well as reduction of pain and edema in soft tissues (Bassett 1989; Markov and Pilla 1995). For musculoskeletal injuries and post-surgical, post-traumatic and chronic wounds, magnetic fields are recognized as a modality that contributes to reduction of edema. It is well known that edema reduction can be a major therapeutic instrument in the acceleration of pain and stress relief. Surprisingly, edema reduction has been reported with low amplitude (in the range of 1-50 mT), low frequency (in the range of 1-100 Hz), and pulsed radiofrequency (27.12 MHz) signals applied to the site of injury/pain (Markov and Pilla 1995; Rosch and Markov, 2004).

HAZLEWOOD AND MARKOV

Static and time-variable electromagnetic fields have been applied with apparent success in the management of pain in a variety of orthopedic conditions, most commonly traumatic bone fractures or surgical osteotomies (Becker and Selden, 1985; Becker, 1990; Miner and Markoll, 1993; Trock *et al.*, 1994; Bassett, 1994). Carpenter and Ayrapetyan (1994) and Rosch and Markov (2004) edited books that provide excellent overviews of the biological effects of electric and magnetic fields. It is clear that this is an emerging field in biology and medicine. Attempts are being made to scientifically document the impact of electric and magnetic fields on biological systems.

The remarkable observations that there are no known adverse effects with using permanent magnets or low frequency EMF stimulation, lends support for the therapeutic use of magnetic fields is (Rosch and Markov, 2004). In addition, the large body of scientific publications supports the notion that magnetic therapy may have utility in the treatment of pain (Foley-Nolan *et al.* 1990 and 1992; Ellis 1993; Trock *et al.* 1993a, 1993b, and 1994; Markov and Pilla 1995; Vallbona *et al.* 1997; Sartucci *et al.* 1997; Sherman *et al.* 1998). However, it should be noted that despite a number of clinical studies performed world-wide indicating successful use of magnetic fields for treatment of various diseases and pathologies, little is known regarding the effectiveness of magnetic fields in relieving low back pain (LBP).

One of us (CFH) has placed magnets on his body in order to test for pain relief. Placing the magnet on the site of the pain experience led to some relief, but never considered satisfactory, except on rare occasions. Upon seeing a figure from Travell and Simons (1983), in a pain clinic, which schematically showed a trigger point at the mid-thigh area near the groin referring pain to the right knee cap, the idea surfaced, that one could possibly “inter the body magnetically” at the site of the trigger point. If that were the case, would pain relief be experienced? The procedure was completed within one and one half hours—the patellar pain (chronic for CFH) completely dissipated. This experience was shared with another physician-scientist, more elaborate experimental designs were considered and executed. Also, by applying the magnets to trigger points of referred pain, volunteer subjects have been relieved of their pain within twenty to forty minutes (Vallbona *et al.*, 1997).

Herein, we discuss the use of static magnetic fields to provide pain relief in specific, and therapy for myofascial problems in general.

Chronic Pain Symptoms

Chronic pain can be defined as pain that persists past the normal time of healing and lasts at least six months. Chronic pain is not only a burden to the individual who must cope with the experience of persistent pain symptoms, but also to the health care system that is often unable to permanently alleviate the suffering experienced by the individual. The experience of chronic pain is a complex mixture of factors that include pathological tissue changes eliciting nociception as well as psychosocial and psychophysiological behaviors elicited by pain. By definition, pain is a subjective phenomenon. Therefore it is well understood that, in order to obtain an accurate assessment of the pain experienced by an individual, a self-report of the pain intensity and symptoms must be considered along with other appropriate medical assessments (Goodman and McGrath 1991).

Even with the rapid, and often successful advances in surgical techniques and non-invasive therapies for the treatment of painful conditions such as low back pain, many individuals suffering from these conditions continue to experience pain after medical interventions have been performed (Mayer and Gatchel 1988). The risk of anesthesia, the length and tolerance of postoperative immobility, and the effects of the biomechanics of the spine have to be considered with respect to possible surgical interventions. Bed rest, anti-inflammatory medications, steroidal injections, and physical therapy programs are often prescribed. In many of these individuals, the incidence of overuse or misuse of medication (Kouyanou *et al.* 1997) and excessive activity limitation (Haythornthwaite *et al.* 1991; Vendrig and Lousberg 1997) are not uncommon pain behaviors.

Myofascial pain: chronic pain in a different perspective .

What is myofascial pain? Let us first say some words about “myofascial problem”. Physiologist have known for relatively long time that each and everyone of the some 400 skeletal muscles in the human

body are surrounded by connective tissue called fascia. For various reasons myofascial problems could occur at the surface of interaction between muscle and fascia, in many cases caused by an inflammation. The demonstration of the problem that occurs might be the appearance of a localized sensation of pain at a given spot of the body which is manifested also at the body surface as a myofascial trigger point. In many cases the trigger point might be distant from the place at which myofascial problem originated. Such trigger points might be found at different areas over the body and when touched the pain might be aggravated. Further, a myofascial trigger point is defined as a hyperirritable spot, usually within a taut band of skeletal muscle or in the muscle's fascia, that elicits a painful experience upon touch (Travell and Simons, 1983, Vol. 1, p. 3). Myofascial pain syndrome is discussed, in detail, through out the two volume set by Travell and Simons (1983, Volumes 1 and 2) entitled: MYOFASCIAL PAIN AND DYSFUNCTION. As pointed out by Travell and Simons, the word "myofascial" was used, as early as 1940, "...to describe the identification and treatment of trigger areas in muscles of the low back and by 1948, in pectoral muscles" (Vol. 1, p. 10). Janet Travell, in 1952, adopted the term *myofascial*. She observed that during an infraspinatus muscle biopsy, stroking or pinching either the superficial fascia or the contractile tissue of the muscle evoked the referred pain pattern from the muscle" (Travell and Simons, 1983, Vol. 1, p.10). In addition, Travell and Simons record that "*The expressions, 'myofascial pain' and 'myofascial syndrome,' have the advantage that they clearly situate the illness in the muscle or its fascia, and that they have been used consistently to identify TP [trigger point] phenomena...*"

Trigger points.

Trigger points may be latent or active and Travell and Simons (1983) define them as "a focus of hyperirritability in a tissue that, when compressed, is locally tender and, if sufficiently hypersensitive, gives rise to referred pain and tenderness..." Thus, a trigger point is a functional, rather than an anatomical, entity. Nevertheless, the identification of trigger points with its referred pain experience, is relatively easy to identify with the Trigger Point Manual of Travell and Simons. When a trigger point is inactive, it is difficult to identify, yet when the process of activation begins the sensitivity of the trigger point becomes greater and greater to touch—hence, easier to identify. This onset of sensitivity may be referred to as a latent trigger point. Note: an active myofascial trigger point is always associated with pain, while a latent trigger point, is not usually associated pain. The latent trigger point, however, may cause restriction of motion and weakness of the affected muscle. The latent trigger point may persist for years after partial recovery from injury has begun. Acute attacks of pain may exist, since minor overstretching, overuse, or cooling of the muscle may serve to reactivate it (Travell and Simons, 1983). In summary, both latent and active trigger points cause dysfunction, and active trigger points cause pain. Finally, it should be recognized that myofascial trigger points are to be distinguished from those of other tissues such as skin, ligaments and periosteum (Travell and Simons, 1983).

Normal muscles do not contain detectable trigger points. Normal muscles have no taut bands of muscle fibers, are not tender to firm palpation, exhibit no local twitch responses, and do not refer pain in response to applied pressure. Males or females of any age can develop trigger points—particularly sedentary, middle-aged women. Except in later years, women seem somewhat more likely than men to develop myofascial pain syndromes. It appears that women are more likely (rather than men) to seek medical aid for pain of myofascial origin (Travell and Simons, 1983).

Active trigger points are more likely to reside in postural muscles of the neck, shoulder, pelvic girdles, and the muscles of mastication. Again, the upper trapezius, scalenes, sternocleidomastoids, levator scapulae and quadratus lumborum muscles are commonly involved. *Myofascial pain is referred from trigger points in specific patterns characteristic of each muscle* (Travell and Simons, 1983). The trigger points, for spontaneous pain, are rarely located in the spatial area of the pain experience. That is, trigger points and the area of the pain experience are spatially displaced. Referred pain of myofascial trigger points usually is described as dull and aching, often deep, with intensity varying from low-grade discomfort to severe and incapacitating. It may occur at rest, or only on motion.

Digital pressure on a given trigger point (or penetrating the trigger point with a needle) elicits referred pain or causes an increase in intensity of that pain. The more hypersensitive the trigger point, the more intense and consistent is the referred pain, and the more extensive and sustained is its distribution. In various myofascial trigger point syndromes, pain is rarely completely symmetrical across the body. At examination, the patient usually complains of pain from the most recently activated trigger point. When this trigger point is eliminated, the pain pattern may shift to that of an earlier trigger point that also must be inactivated. If the initial (or dominant) trigger point is inactivated first, the patient may recover without further treatment. Travell and Simons (1983) point out that Pain referred from myofascial trigger points do not

follow simple segmental patterns, familiar neurological patterns, nor the known patterns for referred pain of visceral origin.

The severity and extent of the referred pain pattern depends on the degree of irritation, and/or inflammation of the trigger point, not on the size of the muscle. Trigger points are activated directly by acute overload, overwork fatigue, direct trauma, and by chilling. Primary myofascial trigger points also develop in muscles subject to excessive repetitive or sustained contractions (overload fatigue). Secondary trigger points are likely to develop in adjacent muscles that are chronically overloaded by spasms. It is well known that active myofascial trigger points vary in irritability from hour-to-hour and from day to day. The amount of stress required to produce myofascial pain is highly variable, compared with other muscular pains, including angina and intermittent claudication, that are due to arterial insufficiency. Trigger-point irritability may be increased *from a latent to an active level* by many factors. The amount of stress needed to activate a latent trigger point and thus cause a clinical pain syndrome depends on the degree of conditioning of the muscle; the greater the exercise tolerance of the muscle, the lower the susceptibility of its trigger points to activation.

Once, knowledge of the referred pain by trigger points was clear, an assumption was made that magnetic fields, applied to trigger points, would reduce or abolish the pain referred by the specific trigger point. The first test of this hypothesis was initiated in pilot study of a small population of subjects with a chronic pain condition known as the Post Polio syndrome. In this clinical setting, the trigger points and their sites of referred pain were well delineated.

Post-polio syndrome.

Overuse of body parts is perhaps the largest cause of myofascial type pain. The magnitude of the population involved with the malady is unknown; however, one well-known group within the broad group of disabilities is the survivors of polio. Within this group is found a sizable number people suffering from both chronic and acute pain: the Post-polio syndrome (PPS). Halstead *et al.* (1985) compiled responses to questionnaires sent in 1985 to polio survivors identified through informal networks. The pain was classified as myofascitis secondary to progressive denervation; and this continues to be reasonable. For example, Trojan and Cashman (2005) point out that "The cause of PPS remains unclear, but is likely due to distal degeneration of enlarged post-polio myelitis motor units.". Subsequent observations, revealed psychological and social effects that cause changes in both quality of life and in lifestyle (Hollingsworth, *et al.*, 2005). In regard to numbers: one of the latest estimates of the size of the population of polio survivors is set at one million. Within that group, the population of people with post-polio syndrome is stated to be on the order of 80% (Elrod *et al.*, 2005) In this project, 75.5% of the patients had muscle pain and 75.4% had joint pain. The types of pain experiences in this group are multiple, including a lot of diffuse muscle and joint pain (Smith and Mabry, 1995). Recovery from the diffuse muscle pain can take many months and requires considerable compliance (Peach and Olejnik, 1991). The joint pain is thought to be due to degenerative arthritis caused by age. Subacute or chronic sacroilitis occurs very often, but many times it is not recognized because other forms of low back pain mask it.

Clinical study of Postpolio Patients. A double blind, randomized clinical trial was conducted in postpolio patients to determine if pain was relieved by application of static magnetic fields applied directly over an identified pain trigger point (Vallbona *et al.* 1997). The devices used in this study were Bioflex magnets (Magnalex, Inc., Corpus Christi, TX) which have a pattern of concentrically arranged circles of alternating magnet polarity. Depending on the area involved, the device was a disc (40 or 90 mm in size), a credit card-sized pad, or a strip. The magnetic field intensity of the device was rated at 500 Gauss at the device surface for the 40-mm disc and the strips. The 90-mm discs and credit-card pads were rated at 300 Gauss at the surface. Placebo devices were of identical sizes and shapes.

Fifty postpolio patients with muscular or arthritic pain participated in this study. Twenty-nine patients (5 males, 24 females; mean age=51.5 years) were randomly selected to receive treatment with the active magnetized device; 21 patients (6 males, 15 females; mean age=55.9) received treatment with the inactive device. Patients were asked to complete a McGill Pain Questionnaire to provide a subjective evaluation of his or her general pain experience (a validated method for analyzing pain). Only one area of pain was evaluated, even though multiple sites may have been present. A trigger point associated with the site of pain was grossly elicited first by finger palpation and then by firm application of a blunt object, which in non-painful areas produced a sensation of pressure but no pain. The patient was asked to subjectively grade the pain at the trigger point on a scale from 1 to 10 (with 1 being the least and 10 being

the maximum). The appropriately sized magnetic or placebo device was placed on the area of pain with adhesive tape for 45 minutes. After removal of the device, the patient was asked to assess the intensity of pain again using the McGill Pain Questionnaire. The proportion of patients in the active-device group who reported a pain score decrease greater than the average placebo effect was 76%, compared with 19% in the placebo-device group ($p < .0001$) (Vallbona, *et al.*, 1997).

Chronic Low Back Pain

Low back pain (LBP) represents an important health problem in which medical costs and lost work capacity are major issues. Disorders of the low back are a major cause of disability of people under the age of 45 (Mayer and Gatchel 1988). In fact, work incapacity resulting from LBP has been estimated to vary between 2% and 8% in Western Europe and North America (Nachemson 1992). The medical costs associated with the treatment of low back disorders have been estimated to fluctuate between \$4.6 and \$60 billion annually in the U.S. (Lee 1994; Miedema *et al.* 1998).

Static and time-varying EMFs have been applied with apparent success in the management of pain in a variety of orthopedic conditions, most commonly traumatic bone fractures or surgical osteotomies (Bassett 1989). Furthermore, in the domain of osteoarthritis several double blind, placebo-controlled studies demonstrated the efficacy of pulsed EMFs for the relief of pain (Trock *et al.* 1993a, 1993b, and 1994).

A large body of scientific literature suggests that magnetic therapy may have utility in the treatment of pain (Foley-Nolan *et al.* 1990 and 1992; Ellis 1993; Trock *et al.* 1993a, 1993b, and 1994; Markov and Pilla 1995; Vallbona *et al.* 1997; Sartucci *et al.* 1997; Sherman *et al.* 1998). However, it should be noted that despite a number of clinical studies performed world-wide indicating successful use of magnetic fields for treatment of various diseases and pathologies, little is known regarding the effectiveness of magnetic fields in relieving LBP.

In the experimental design, trigger points were identified for the subject's pain experience. Magnets of a specific design were placed over the trigger points responsible for the pain experience. These magnets had been charged to surface field strengths between 300 to 500 Gauss and were disc-shaped. The disc magnets can be kept in place by means of adhesive tape and/or specially made double sided adhesive, which is attached directly to the disc surface. It is clear from initial studies that the application of the magnets to a trigger point can reduce or eliminate (by subjective measure) the pain referred from that trigger point. The mechanisms of the effect of magnetic fields on soft tissues have not been elucidated.

The hypothesis

One of us (MSM) have been studying the biological and clinical effects of magnetic fields for several decades. The hypothesis for "biological windows" have been proposed in 1976 and further developed. This term refers to existing preferred values of magnetic fields that cause significant biological response. It appears that Mother Nature, during evolution, created mechanisms for response at which selected magnetic fields are detected, while living creatures neglected other signals, which could be even stronger (Markov, 1994). The existence of such windows have been proven in studies with various living systems as well as with different systems in human body. Probably we should speak about "biophysical windows" instead of "biological windows". The difference should be that this idea is more related to the physical parameters of the applied endogenous signal rather than to biological characteristics. From a biological point of view, one plausible mechanism could be linked to the idea proposed by Blank (2004), who reported existence of a domain in the heat shock protein HS70 that is responsible for detecting the MF signal.

We are proposing a hypothesis that trigger points represent a real biological "window" or "door" for delivering the magnetic field to the muscles or other body parts that experience pain. Let us make a following model: The part of the body that represents an activated trigger point virtually could open the door for any physical influence. When appropriate magnetic field is applied, like a key for the locker, the door "opens" and allows the magnetic field, virtually to enter the body. Next, via the systemic effect (presented by us at Kos meeting 2003), the signal is delivered to the source of the problem – where irritation, inflammation, or some other pathophysiological disturbances took place. In that part of the body, inflammation may invoke T-lymphocytes for fighting the inflammation. As it was shown, by one of us, at the Rhodes meeting (Nindl *et al.*, 2002) and in our recent publication (Markov *et al.*, 2006), magnetic fields more significantly influence the lymphocytes activated by the disturbances.

HAZLEWOOD AND MARKOV

This hypothesis might be summarized as follows:

- ❖ A trigger point becomes activated due to inflammation at the interface between muscles, and fascia
- ❖ If an appropriate magnetic field is applied, the trigger point secures the pathway for the magnetic field
- ❖ Via systemic effect, the signal is delivered to the source of inflammation (i.e., the interface between muscle and fascia)
- ❖ Magnetic fields stimulate those T-lymphocytes that have been activated by inflammation, thus reducing the inflammation and, in turn, bring about pain relief.

We also postulate that, there could be a change in the tensile properties of cartilage, ligaments, and other soft tissue structures, which secondarily may relieve tension on arthritic joints or on chronically "inflamed" areas. Such ideas seem very possible in light of the work of Becker and Selden (1985) and Vallbona, *et al.* (1983). That the magnetic fields interact with the biological "transmission lines" contained within the trigger point area; and, that the "transmission lines" possibly communicate with the inflamed area of the pain experience. Such speculation is consistent with the concept of the systemic effect (Ericsson, *et al.*, 2005) (Markov, *et al.*, 2006).

Continuing with this line of thought, we remind the reader that connective (i.e., the extracellular matrix) has been suggested to be involved in myofascial pain as well as in pain relief. As discussed above, a network of connective tissue surrounds each muscle fiber of a given muscle, all muscle groups (arms, legs, trunk, head, and neck), all nerve fibers, neuromuscular junctions, etc. (Fawcett, 1994, Chapters 5, 10, and 11; Barker, 1974). It has been hypothesized that contraction-relaxation units exist throughout the extracellular matrix of the body (Hazlewood, 2003). It is proposed that shortening of these "units" do induce pain, and relaxation of these "units" do induce pain relief. For myofascial type pain the possibility of the involvement of the connective tissues as a player in various pain syndromes is reasonable.

In conclusion: We realize that the speculations put forth in this presentation may be a little overwhelming. Nevertheless, we ask for your indulgence--please remember, these speculations are intended to provoke both thought and experimentation. Note: We are searching for an explanation of the observation that the probability of pain relief is enhanced when a magnet is placed over a trigger point as opposed to direct placement on the painful area; and, therefore ask the question: Could trigger points serve as a sensitive "tissue window" providing pathways of stimulation to the needed area?

Abstract

The ability to manipulate volumes of liquid and their constituent components, such as cells, organelles and their nucleic acids, utilizing very small (microliter) sample volumes provides new and novel opportunities and capabilities in microchip based bio-analysis and detection or lab-on-a-chip based diagnostics. The low sample volume requirements and rapid real-time processing capability enables parallel and multi processing capability without adverse impact on sample degradation.

Our research effort has focused on the development and application of non-invasive cell manipulations and separation techniques to facilitate fraction of diseased and healthy cells on a microchip in a rapid fashion with minimal amount of sample preparation. The cell sample processing capability is provided by electrokinetic based manipulation on-chip by leveraging the phenomena of dielectrophoresis (DEP). We explore the integration of electrokinetic methods for both particle and liquid manipulations utilizing conventional “closed channel” microfluidic structures as well as surface fluidic or “open channel” schemes.

Utilizing closed channel microfluidic structures, we have demonstrated DEP cell separation capability on batch and continuous flow through samples. We have furthermore explored the combined use of liquid and particle DEP to provide alternate means of processing/manipulating micro litre sized liquid droplets containing cells. This cell sample preparation capabilities provided by the integrated DEP and microfluidic, when integrated with other downstream processing components, such as cell lyses, genetic amplification and nucleic acid detection capability, has the potential of providing a complete bio-analysis on a chip. The proposed platform technology is not limited to applications targeted to disease detection; it is equally suitable for the detection of environmental agents and pathogens that have adverse impact on human health. Furthermore, the technology makes available useful small sample handling and analysis capabilities, which can be leveraged to benefit investigations concerning interaction of E.M. fields with biological cells.

1. Introduction

In recent years, as a result of advances in microfabrication methods, materials and process technology and coupled with its availability to the research community has resulted in many new and novel application of the technology in many diverse areas in addition to the traditional semiconductors and microchip industry [1, 2]. For example the ability to lithographically pattern and etch microscopic scale micro-channels in glass provided a compact footprint for the development of capillary electrophoresis, with improved sample handling, detection and throughput [3]. Furthermore the miniaturization of such devices has made it possible for their infield deployment and handheld operation. Despite the success of such development in fluidic microsystems, a number of issues and obstacles need to be addressed before the technology can be considered reliable and mature enough to be applied successfully in the more critical and demanding arena of biomedical diagnostics, on a routine basis. Of major concern and a significant challenge in this regard is the availability of suitable on-chip low volume sample preparation and handling methods [4, 5] in addition to suitable sample isolation (valving), pumping, mixing components.

Recent advances in the development and application of A.C. electrokinetics has shown that simultaneous handling and manipulation of very small quantity of fluids and particles, such as cells can be achieved utilizing the traditional closed channel microfluidic and more recently open channel surface microfluidic devices [6]. In the past, A.C. electrokinetic systems leveraging the phenomena of Dielectrophoresis (DEP) have been developed

primarily employing closed fluidic chambers or microfluidic channels and intersections that are interfaced to external fluid pumping and sample injection hardware [7-9]. Such systems, particularly those employing microfluidic channels for cell collection and separation usually require sample preprocessing and are frequently plagued by micro-channel blockage. Such problems need to be overcome in order to successfully commercialize microfluidic cell analysis/sorting devices. The closed channel microfluidic systems are furthermore less amiable to creating complex cell processing structures, due to pressure and flow related problems and the need for extensive valving and flow control devices on-chip and capable of withstanding high operating pressures. In the paper we discuss the utility, application and merits of example “open channel” or surface microfluidics and “closed channel” microfluidic systems for biological cell sample handling and analysis utilizing A.C. electrokinetic approaches.

2. AC electroactuation and manipulation of cells and microfluids by dielectrophoresis (DEP)

Electrical field effect phenomena have been extensively investigated and demonstrated to provide novel ways of manipulating and interrogating individual microscopic sized particles and intact biological cells, immersed in fluid media [10-12]. In this paper we focus on the capabilities and utility of non uniform A.C. (alternating current) electric field effect, referred to as dielectrophoresis (DEP), in providing particle, liquid, droplet actuation at microscopic scales to facilitate the deployment of fluidic microsystems or LOC for the handling and manipulation of cells and subsequently the genetic material of the individually selected or fractionated cell population.

(a) Particle DEP actuation

To illustrate the salient features and basis for particle DEP actuation, consider a microscopic sized spherical shaped particle or object that is immersed or surrounded by another medium and subjected to an externally imposed non uniform electric field. We further assume that the particle and the surrounding medium are characteristically different in terms of the electrical permittivity and conductivity. The time averaged DEP force $\langle \vec{F}_{DEP} \rangle$ acting on a spherical body of radius a , due to a spatially non uniform ac electric field, is summarized as follows [13]:

$$\langle \vec{F}_{DEP} \rangle = 2\pi\epsilon_m a^3 \text{Re}[K_e] \nabla E_{rms}^2 \quad (1)$$

$$\text{where, } K_e = \frac{\epsilon_p^* - \epsilon_m^*}{\epsilon_p^* + 2\epsilon_m^*}$$

In the DEP force expression (Eqn. 1), the quantity $\text{Re}[K_e]$ refers to the real part of excess polarizability or frequently referred to as the Claussius-Mosotti factor (CMF). The quantities $\epsilon_p^* = \epsilon_p - j\frac{\sigma_p}{\omega}$ and $\epsilon_m^* = \epsilon_m - j\frac{\sigma_m}{\omega}$ are the complex permittivity of the particle and medium respectively. ϵ_m , ϵ_p represent the real dielectric permittivity of the medium and particle σ_m , σ_p refer to the conductivity of the particle; and the medium and $\omega = 2\pi f$ is the radian frequency, where f (Hz) is the applied A.C. electric field frequency. The CMF reflects the polarizability difference the particle and media, and is usually a sensitive function of the applied field frequency. The term ∇E_{rms}^2 is the gradient of the electric field squared.

It is apparent, from Eqn. (1), that the DEP force depends on the particle size (volume), the gradient of electric field squared and the Claussius–Mosotti factor which is frequency dependent. Furthermore, when $\text{Re}[K_e] > 0$, at a particular frequency, the DEP force is positive (+ve DEP) and directed towards the region of increasing field intensity [12]. In contrast, when $\text{Re}[K_e] < 0$, the DEP force is negative (-Ve DEP) and impels the particles to regions of field intensity minimum [14]. The impact of +Ve and -Ve DEP forces acting on particle subjected to nonuniform field, as synthesized by a set of coplanar electrodes, is shown schematically in Figure 1. The +Ve and -Ve DEP effect has the beneficial effect of physically separating or concentrating the particles in regions of field intensity maxima (at the electrode surfaces) and minima (located away from the electrode surfaces). Most microscopic particles of practical interest, including biological cells, due their structural heterogeneity and differences in the electrical properties of the various ultra structures compared to that of the suspending media may exhibit both +Ve and -Ve DEP behavior in different region of the applied field frequency spectrum [15]. It is due to such characteristic differences in the frequency dependent polarization and the resulting DEP response which enables selective and differential manipulation and physical separation of one or more types of particles or cells in a mixed population suspension.

Figure 1. A cross-sectional view of a co-planar electrode geometry, showing the differing +Ve and –Ve DEP forces exerted on particles, induced by a nonuniform AC field, as depicted by the dashed lines the diagram. The shaded particle, experiencing +Ve DEP, are impelled towards and collected at the electrodes, while particle experiencing –Ve DEP body force is impelled upwards into a region of local field intensity minima.

(b) Liquid DEP actuation and droplet dispensing

The utility of the DEP effect is not limited to particulate matter, but maybe made to manifest and exert body forces on aqueous polarizable media [14-16]. The practical and useful utility of the phenomena, especially at the micro scale, enables novels means of handling and manipulating aqueous biological fluid samples, without the need for valving and/or pumping required for isolation, steering and fluid transport in conventional microfluidic systems. Thus, the DEP effect, in addition to serving to electro-actuate microscopic particles and thereby facilitate their manipulation may furthermore be leveraged to enable noninvasive handling and manipulation of microliter volume droplets of aqueous dielectric media on open surfaces. Such open surface manipulation of biological samples circumvents a variety of issues that plague closed channel systems.

The first demonstration of macro scale liquid actuation by DEP was reported by Pillet [16]. By partially immersing two parallel plates in a bath of aqueous dielectric media (oil) and applying an A.C. potential to the plates, he observed that a column of liquid was raised between the plates to a new equilibrium.

More recently, the work of Jones et al [17, 18], Ahmed et al [19] and Kanagasabapathi et al [20] have shown that similar type of controlled actuation of a small quantities of dielectric liquids (oils and low conductivity water), on top of planar surfaces can be achieved by employing a pair of thin coplanar metal electrodes, coated with a thin film dielectric material, of a suitable contact angle ($< 70^\circ$), as shown in Figure 2.

For satisfactory operation, liquid that is to be actuated and dispensed is usually introduced as a parent drop at one end on the electrode structure. On application of an AC voltage, typically $\sim 230V_{RMS}$ @ 100 kHz, a jet of liquid in the form of finger, confined to the width of the electrodes, protrude from the parent droplet and very rapidly extend to the end of the electrode structure.

The characteristics of this liquid finger formation has been analysed by Jones et al [21]. A reduced-order lumped parameter model was proposed that takes into account liquid surface tension viscous drag, and the DEP force. The resulting expression, describing the DEP force induced on the liquid finger, is as follows [19]:

$$F_{liquid\ DEP} = \frac{(\epsilon_{liq} - 1)C_d^2 C_{air} V^2}{2(C_d + 2\epsilon_{liq} C_{air})(C_d + 2C_{air})} \quad (2)$$

The liquid DEP force imparted, varies as the square of the applied voltage (V), the permittivity of the liquid (ϵ_{liq}) and the characteristics of the field in the liquid media, controlled by the electrode structure, dielectric coating and geometry. Upon removal of the voltage, the liquid finger breaks up into one or more smaller sized daughter droplets that are spaced almost uniformly on top of the electrodes. Further refinements in the basic coplanar structure, such as a three electrode system, the judicious location of semicircular metal bump areas and their spacing to satisfy the Raleigh jet break criterion have enabled the controlled dispensing of aqueous media (deionized water) in the form multiple identical sub-microliter droplets [19]. These are included in the structure shown Figure 3(a), while figure 3(b) shows the daughter droplets populating the metal bump regions spaced at regular intervals along the coplanar electrode structure.

Figure 3. (a) Photographs showing the 3-electrode structure with metal bumps, for improved droplet formation. (b) Successful population of the bump regions with smaller daughter droplets after the applied voltage is removed.

Figure 2. A schematic (a) plan and (b) cross-sectional views of the co-planar electrode geometry, coated with a thin dielectric film, employed for DEP actuating liquid. Nominal dimension of the structure are as follows: $t \sim 0.5 \mu\text{m}$; $w = 30 \mu\text{m}$; $g = 30 \mu\text{m}$.

Thus, successful development and implementation of liquid actuation, droplet formation and transport on open surfaces utilizing liquid DEP, open up a variety of new application in the microfluidics domain concerning the manipulation of minute quantities of fluid sample and its components. Some such example surface fluidic manipulations are discussed in a later section in this article.

3. Integration of on-chip DEP with microfluidics

Having provided a basis for DEP manipulation of particles and liquid samples, we now turn to its application and utility for lab-on-a chip applications. In this article we specifically focus on microfluidic devices that integrate DEP for particle/cell handling or processing. The level and extent of the integration effort demanded is very much governed by the application (i.e. application specific). For example, a fully integrated microfluidic device for chip based genetic analysis requires a number of different microfluidic component blocks to facilitate cell manipulation, nucleic acid processing (genetic amplification and separation) and a suitable electro-optical detection system. More specifically a fully integrated platform would include cell sorting and fractionation and/or concentration, cell lysis step to extract the genetic material (DNA, RNA), genetic amplification procedure, such as on-chip PCR and subsequent DNA separation and detection utilizing on-chip capillary electrophoresis.

Thus on-chip sample preparation, including cell separation, is a key and much needed capability that can have a dramatic impact of the overall performance and capabilities of integrated microfluidic chips for bio-analysis and detection. In the past a variety of different techniques methods have been proposed to handle the sample preparation needs, however, many of the proposed approaches, unlike DEP are not readily incorporated on-chip. Here we examine two different approaches, a batch sorting scheme and a continuous DEP based cell fractionation in affecting cell separation in microfluidic channels. A fundamental requirement of all devices that leverage DEP is appropriate synthesis of a nonuniform electric field, which is achieved quite readily using metal electrodes of appropriate dimension, spacing/geometry. However, in order to integrate DEP electrode structures in microfluidic channels, we are limited to the use of planar electrode structures which can be photo lithographically patterned. Furthermore, to facilitate microfabrication, the planar electrodes are limited to locations on the top or bottom sides of the microchannels. The choice of material for the metal electrode material has to be given due consideration. If the channels contents are to be visually inspected or the contents monitored, then it is appropriate to transparent electrodes material such as indium tin oxide (ITO), otherwise either titanium-platinum or chrome-gold electrodes have been shown to suitable and readily deposited and patterned lithographically.

An example of a DEP based microfluidic chip fabricated to make available binary DEP fraction of cells in a continuous fashion [22], is shown in Figure 4.

Figure 4 A closed channel microfluidic DEP fractionation chip, showing the microfluidic channels with in-channel microelectrodes for DEP cell sorting

Figure 5. Plot of the DEP velocity spectrum of viable and nonviable yeast cells versus frequency. showing +Ve DEP and -Ve DEP responses [21].

The device is comprised of a cell and sheath injection ports that facilitates the injection of a cell sample into the chamber using off-chip pumping. The dimensions of the sheath flow and cell sample channels are designed to enable hydrodynamic focus of the cell stream under laminar flow. The focused injected cell stream is subjected to a nonuniform isomotive electric field, synthesized by an array of individual biased electrodes. In this isomotive field region cells, depending on their frequency dependent polarizability, may experience positive or negative DEP depending on the frequency of the applied field, and hence are deflected in opposite directions and

normal to the fluid flow. Thus cells experiencing +Ve and -Ve DEP are physically separated and subsequently collected as purer subpopulations downstream. Example DEP spectral of viable and non-viable yeast cell, obtained using the device is shown in Figure 5. The plot reveals that binary fractionation of viable from nonviable yeast cells, suspended in deionized water, and is most efficiently attained over specific regions (10 kHz to 80 kHz and 1 MHz to 5 MHz) of the frequency spectrum. Further integration of the chip, incorporating near-field hybrid attached to the glass substrate facilitates real-time monitoring of cell separation at the outlet ports of the device [23].

An alternative approach to the continuous fraction of cells utilizing DEP is to adopt a batch sorting /separation which is perhaps more suitable in cases where a dilution of the cell sample concentration by the sheath flow as in the continuous separation is not desirable. An example of this batch cell separation device is shown in Figure 6. Unlike the continuous cell sorting device, requiring metallized electrodes on the top and bottom faces of the microfluidic channels, the batch scheme can be readily implemented with an array of electrodes house on a glass substrate while the microchannels enclosing the electrodes are cast in Poly(dimethyl siloxane) (PDMA) and affixed on top of the glass substrate[24]. The use of PDMS polymer for microfluidics, is advantageous as it reduces the time, complexity and cost of prototyping and manufacturing. PDMS is hydrophobic and can easily nucleate air bubbles, however, by exposing the cured PDMS layer to oxygen plasma at a pressure of 0.15 torr renders the surface hydrophilic and makes it compatible for microfluidic handling. The assembled microfluidic DEP device can withstand moderate chamber pressures, typically ~ 30-50 psi.

In such a batch DEP device, a dilute cell suspension is introduced in to the chamber employing pressure driven flow and an AC voltage is applied to the electrode array. Cells experiencing +Ve DEP are collected in the high field regions, while cells experiencing negative DEP are repelled from the electrode surfaces and levitated or trapped in local field intensity minima (see Figure 7). Since the +Ve DEP cells are strongly held on to the electrode surface and the -Ve DEP cells can be flushed while retaining the cells collected at the electrodes in the chamber. Such batch DEP devices, although simple in design compared to the continuous cell sorting system, finding utility in applications that require concentration of cell sample into a smaller volume.

Figure 6. A glass-PDMS microfluidic device for batch DEP cell separation with in-channel planar interdigitated microelectrodes electrodes (electrode width = 20 μm ; electrode spacing= 20 μm)

Figure 7 Photographs showing(a) microscopic sized latex beads (10 μm in diameter) suspended in low conductivity media (water) exhibiting -Ve DEP and levitation above the electrode plane and (b) +Ve DEP collection of yeast cells at electrode edges [23].

4. Surface Fluidic Structures for Integrating Liquid and Particle DEP

Conventional microfluidic devices or systems to a large extent are comprised of microfluidic channels, which traditionally are etched in glass or more recently patterned in PDMS or other suitable polymeric substrates. The substrate with the etched channels are then suitably bonded or sealed to another or identical substrate material to form closed microchannel structures. As discussed earlier there are a number of issues concerning the utility and applicability of such devices in the domain of microfluidic when handling or processing of aqueous biological sample containing cells or macromolecules in suspension. Recently, the emergence of Liquid DEP as alternate means of manipulating and processing small quantities, has suggested new and novel schemes of manipulating liquids samples comprised of cell (cell suspensions), macromolecules and/or reagents.

An example surface fluidic structure illustrating the combined manipulation of both liquids and particles (cells) utilizing Liquid and particle DEP phenomena [19] is illustrated in Figure. 8. The microelectrode structure basically combines the liquid actuation and droplet formation station with the particle DEP microelectrode array. The key capabilities of this integrated structure are (1) its ability to dispense and form droplets of a cell suspension at locations as specified and implemented by the Liquid DEP structure (2) the ability to subject cells suspended in the daughter droplets, formed by liquid actuation, to one or more DEP field frequencies and subsequently convey the sample to another location in the structure. The structure illustrated in Figure 9 was microfabricated integrating different electrode arrangements at the bump regions.

Figure 8. A schematic diagram of surface fluidic structure integrating liquid and particle DEP [20].

Figure 9. Photograph of the fabricated surface fluidic structure for the combined DEP manipulation of liquid parent droplet and particle within the daughter droplets. Four different electrode arrangements are incorporated in the structure for DEP manipulation of particles.

To verify the particulate DEP effects on open droplets, sample media containing yeast cells (*Saccharomyces Cerevisiae*) placed directly on the bump region. An AC voltage of $2.47 V_{RMS}$ was applied at 600 kHz, yeast cells were observed to be pulled towards the electrodes and furthermore forms pearl chain along the periphery of the bump region due to +Ve DEP effect (Fig. 10a). However, at frequencies above 10 MHz, the same cells were repelled from the electrode periphery (-Ve DEP) as in Fig. 10b. Under -Ve DEP conditions, some cells are trapped within the interdigitated electrodes, this phenomenon though not quantified can be attributed to the smaller electrode gaps resulting in very high particle-particle interaction and thereby forming cell-traps. Cells repelled under -Ve DEP conditions were actuated along the electrodes below the bumps, forming picolitre droplets on the lower bumps.

Since liquid actuation, droplet formation and subsequent particle DEP are achieved in rapid fashion, we are

presently engaged in the integration of near-field optical sensors to detect the presence of a liquid finger, droplets and particle (cell) at suitable locations in the structure.

The combined liquid actuation with droplet formation and multi-frequency DEP examination of cell suspension sample, as well as providing novel opportunities of providing sample preparation, including sorting, analysing and/or separation of cells.

Figure 10. (a) The +Ve DEP of yeast cells at an applied voltage of 2.47 V_{RMS} and frequency 500 kHz; (b) -Ve DEP of yeast cells at 10 MHz [20].

5. Integration of Liquid/particle DEP with genetic amplification (PCR) and detection

Having demonstrated the particle and liquid handling, we now focus on the integration of other additional liquid handling or processing capabilities necessary to implement genetic amplification utilizing PCR and detection. A fundamental requirement, in addition to thermal cycling, is the mixing of the sample with reagents and buffers. To demonstrate such mixing capabilities we employed DEP liquid actuation to project a finger from the parent droplet housed on top of the coplanar electrodes (see Figure 11) [25]. The electrodes were designed such that they terminated on the edge of a sample well containing PCR mix. The PCR well was coated with Teflon to minimize DNA adsorption and further aided in preventing the liquid in the PCR from forming a finger. Thus once an AC voltage (230V, 100 kHz) was applied to the coplanar electrodes a liquid finger was actuated from the parent drop containing known template DNA and contacted the PCR mix in the well, approximately 10% of the sample DNA was transferred to the PCR well. The chip was then thermal cycled 20 times to amplify the template DNA, transferred by finger actuation into the PCR well. The PCR amplified product was analysed by on-chip capillary electrophoresis to verify the presence of template DNA in the mixed and amplified sample. This is the first demonstration of a microfluidic chip that integrates DEP actuated surface fluidic sample mixing, with conventional closed channel well PCR and CE detection. These findings suggest novel ways of combining the sample preparation afforded by DEP on surfaces with the closed channel amplification and detection on a common substrate.

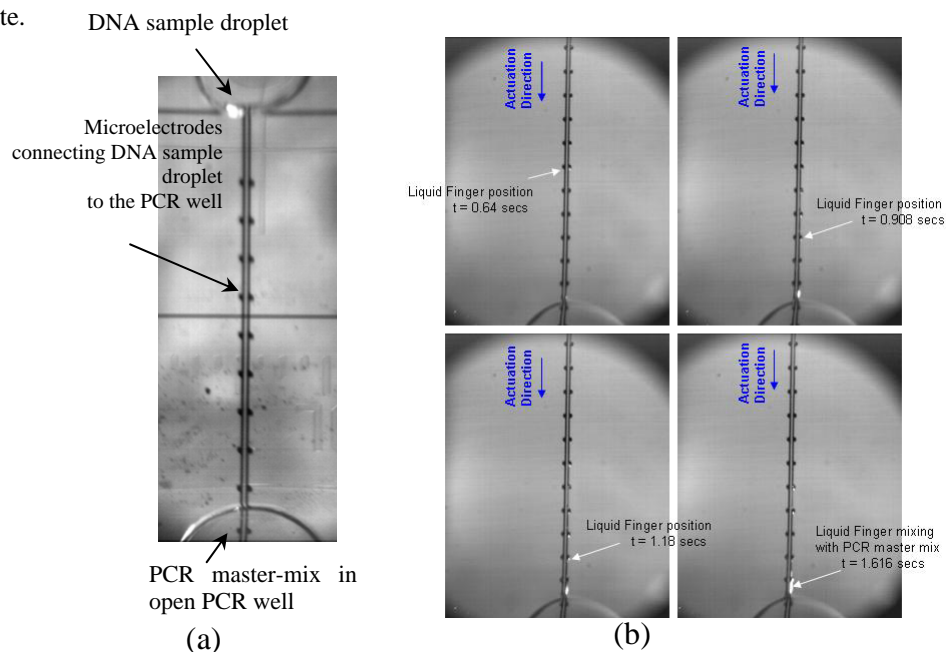

Figure 11. (a) Liquid mixing structure, showing sample and PCR drops located at the end of the Liquid DEP actuation structure. (b) Time sequence of liquid finger drawn from the sample drop and mixed with PCR drop in an open PCR well [25].

An alternative approach to the liquid DEP actuated mixing, as illustrated earlier, is to utilize a whole droplet actuation scheme. The actuation of small droplets confined on top of coplanar electrodes is readily achieved by coating the surface of the electrodes with a hydrophobic coating, such as Teflon. The dimensions of the electrodes are based on the droplet volume to be actuated. Unlike the liquid DEP assisted mixing, achieved by employing high frequency fields, whole droplet actuation and transport is achieved at much lower field frequencies [26]. To illustrate whole droplet mixing approach, two drops, one larger (5 μL) than the other (1.5 μL) were placed onto at the ends of a coplanar electrode structure, coated with SU-8 + Teflon film (thickness $\sim 1.6 \mu\text{m}$). The contact angle of the water droplets on the Teflon coated surface was 110° . When an AC voltage (93 V_{RMS} @ 90 Hz) is applied, the smaller (1.5 μL) droplet was conveyed (35.62 mm/sec) towards the larger droplet, located at the opposite other end of the electrode structure. As the droplet is transported along the electrode track, it exhibits small lateral oscillations. A time sequence showing such actuation of the whole droplet is shown in Figure 12. The ability to actuate whole microliter sized droplets and successfully mix them is particularly important when dealing with protein and enzyme samples, which tend to rapidly collapse, due to adsorption when placed on hydrophilic surfaces.

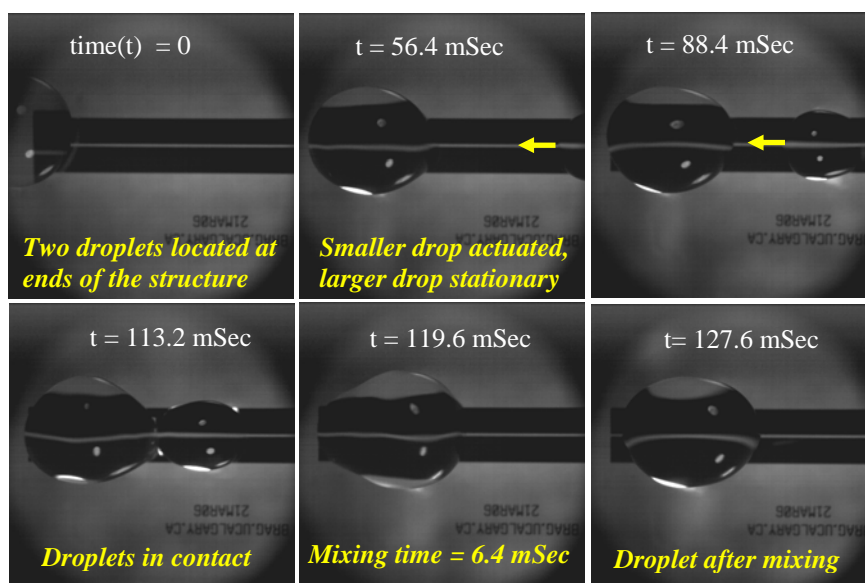

Figure 12. A sequence of photographs, showing the electro-actuation of a μL drop of water. The larger stationary parent drop is mixed with an actuated smaller daughter drop. The details of electrode structure and surface treatment are as follows: Electrode width = 500 μm , Gap = 50 μm and Length = 7700 μm ; Surface dielectric coating: SU 8-2000.5 + Teflon ($\sim 1.6 \mu\text{m}$)

6. Conclusion

In this paper we have illustrated both the phenomena of DEP and its practical utility in potential lab-on-chip devices for clinical diagnostic and laboratory applications in the life sciences. These DEP-microfluidic devices provide the on-chip capability of selective and non-invasive manipulation of cells (trapping, levitating, sorting, concentration, purification) in suspension in closed channel microfluidic devices. We have furthermore reviewed new approaches in liquid and particle processing employing DEP forces, generated by co-planar microelectrodes, for combined particle and liquid actuation on top of open surfaces (surface fluidics). This combined liquid/particle processing capability provides unique handling and processing of biological samples in a rapid fashion. We have specifically illustrated this capability in parallel multi-frequency DEP cell fractionation device, which can serve as the front end sample preparation stage of a more complex lab-on-a-chip devices, target for example genetic finger printing and analysis.

Abstract

Today, the use of implantable cardiac pacemakers has become more widespread and more than 50,000 devices are implanted in Japan per year as of 2005. Implantable cardiac pacemaker patients are excluded from the recommended electromagnetic fields (EMF) level of guidelines such as ICNIRP reference levels. Recently, many communication devices including Radio Frequency Identification (RFID), Electronic Article Surveillance (EAS), and contactless IC cards have been introduced to our daily lives. They are expected to achieve more widespread applications. Accordingly, the assessment of EMF exposure limits for pacemaker patients should be required to complement the EMF safety guidance.

In this paper, electromagnetic interference (EMI) from commercially available RFID reader/writers on implantable cardiac pacemakers and cardioverter-defibrillator (ICD) were investigated. The newly constructed in-vitro experimental test system based upon an Irnich's flat torso phantom was applied. EMI test experiments on 10 types of RFID reader/writers and 13 types of implantable pacemakers and ICDs were conducted. Frequency bands were 125 kHz and HF (13.56 MHz), as well as UHF (950 MHz) and 2.45 GHz. In addition, electromagnetic field distributions of RFID reader/writer antennas were measured in detail. Finally, results of in-vitro EMI test experiments were introduced and characteristics of interferences were discussed.

Introduction

ICNRP guidelines for limiting human exposure were published in 1998 for the purpose of protecting electromagnetic fields (EMF) effects for health [1]. These guidelines include reference levels for occupational and general public exposures. However, these guidelines do not apply to people who wear implantable medical devices. To prevent electromagnetic interference (EMI) on the functions of these devices, it is necessary to find out the conditions which cause malfunctions. A lot of research is being carried out with an increasing in the use of wireless communication devices. In particular, EMI due to mobile phone systems are investigated precisely [2]-[8]. In Japan, guidelines to prevent the EMI is provided and operated under technical report [7].

Radio frequency identification (RFID) technologies are assumed to have widespread application as an automatic recognition method in ubiquitous networks. Scope of the technology includes product management and identification instead of the conventional barcode technology. RFID systems are essential devices to achieve future ICT society.

Several frequency bands, some modulation methods and many types of antenna are employed for RFID systems. For the various types of systems, the effect on implantable cardiac pacemakers and implantable cardiac-defibrillators (ICD) patients should be precisely taken into account. Table. 1 indicates ICNRP reference levels at operating frequency bands of RFID systems. In order to assess the EMI from RFID systems, EMF strengths which cause effects for operations of these devices are required to be examined from experimental and measured results. Then, these threshold field strengths can be compared with the reference levels.

EXPERIMENTS TO ASSESS EFFECTS FOR PACEMAKER PATIENTS

Table 1
ICNRP reference levels for general public exposure to time-varying electric and magnetic fields.
Field strength at RFID operating frequency bands.

Frequency bands	E-field strength (V/m)	H-field strength (A/m)	B-field (μ T)
125 kHz	87	5	6.25
HF (13.56 MHz)	28	0.073	0.092
UHF (950 MHz)	42	0.11	0.14
2.45 GHz	61	0.16	0.20

In this paper, in-vitro experiments to assess the electromagnetic field effects due to RFID reader/writers on both pacemakers and ICDs patients are discussed. First, test experiments to obtain EMI characteristics of pacemakers and ICDs are investigated. Combinations of 13 types of implantable devices and 10 types of commercially produced RFID reader/writers are tested using a newly developed test system. Secondly, to obtain the field strength for the estimation of EMI, radio waves from RFID reader/writer antennas are measured precisely. Finally, experimental results are introduced and characteristics of the EMI are discussed.

In vitro electromagnetic interference test experiments

To obtain EMI data and characteristics of RFID reader/writer antennas, test experiments on 10 types of commercially available antennas and 13 types of pacemakers and ICDs are carried out. Tested pacemakers and antennas are shown in Table 2 and Table 3. Pacemakers and ICDs have many operating modes and functions - pacing/sensing polarity, single/dual chamber mode, and antitachycardia functions. The total test mode is 768 modes at different function modes, frequency bands and RFID reader/writer antennas.

The test system is based upon the previously proposed one for the estimation of EMI due to mobile phones described in [2], [3], [5] and [10]. The system is also employed in EMI test experiments reported by Ministry of Internal Affairs and Communications (MIC) of Japan [8] and [9]. The test system consists of a flat human torso phantom, an electrocardiogram (ECG) signal generator/detector, a chart recorder, an oscilloscope, a measurement platform and a RFID reader/writer antenna as shown in Fig. 1, Fig. 2 and Fig. 3.

The torso phantom used in this experiment is some modifications of Irnich's model in the reference described above. Both atrial and ventricular electrode are improved which enables us to separate each chambers' ECG signal levels of more than 20dB. It is therefore taking advantage to examine EMI with low interference by another chambers' signal. In addition, the size of the phantom is slightly different. The tank of the phantom is made of acrylic material and filled with a saline solution (NaCl 1.8g/L). At low frequency, the saline solution provides same electric conductivity 0.2 S/m as human bodies. This means ECG signals between lead wire of a pacemaker and electrodes go through without direct connection. In addition, it is known this concentration of saline solution gives less attenuation constant than actual human body at radio frequency [5]. The torso phantom is suitable for the EMI test experiment, because it allows more conservative results for EMI estimations.

RFID systems are typically operated at the frequency bands - 125 kHz, HF (13.56 MHz), UHF (950 MHz) and 2.45 GHz, as shown in Table 3. Furthermore, these antennas usually have different shapes, locations and radiating fields depending on their purpose, operating frequency bands and their manufacturers. Moreover, positions between a human torso phantom and RFID reader/writer antennas must be determined precisely and be variable. It is required to measure the EMI due to various antennas with accuracy and repeatability. The two-axis sliding measurement platform shown in Fig. 2 enables us to measure RFID antennas moving parallel to the torso phantom (y-axis direction), while maintaining the same distance between the phantom and antennas (x-axis direction). All parts of this platform are made of dry wood. This system has advantages of high efficiency and data obtained can be reliability assessed.

The number of each RFID system is shown in Table 3. 125 kHz and HF band RFID systems employ amplitude-shift keying (ASK) as modulation method. HF band systems are also compliant with ISO/IEC15693 international standard [11]. In addition, modulation method of UHF band and 2.45 GHz RFID systems are double sideband (DSB) ASK or single sideband (SSB) ASK and frequency hopping spread spectrum (FHSS) or ASK, respectively. EPC Class 1 Generation 2 [12] for UHF band, ARIB STD-T81 [13] or RCR STD-1 [14] for 2.45 GHz are applied as specifications, respectively. In lower frequency bands such as 125 kHz and HF band, an inductive coupling between reader/writer antennas and tags realize their communications. On the other hand, the UHF band and 2.45 GHz systems use electromagnetic waves to communicate with each other. Owing to this dissimilarity, the test procedure introduced in the next section is different.

Table 2
Pacemakers and implantable cardioverter-defibrillators.

Tested devices	Type of chambers	Number of devices
Pacemaker	Single chamber	5
	Dual chamber	5
Implantable	Single chamber	1
Cardioverter-Defibrillator	Dual chamber	2
Total		13

Table 3
RFID reader/writer antennas.

Frequency bands	Modulation methods	Number of antennas
125 kHz	ASK	4
HF (13.56 MHz)	ASK	2
UHF (950 MHz)	DSB-ASK or SSB-ASK	2
2.45 GHz	FHSS or ASK	2
Total		10

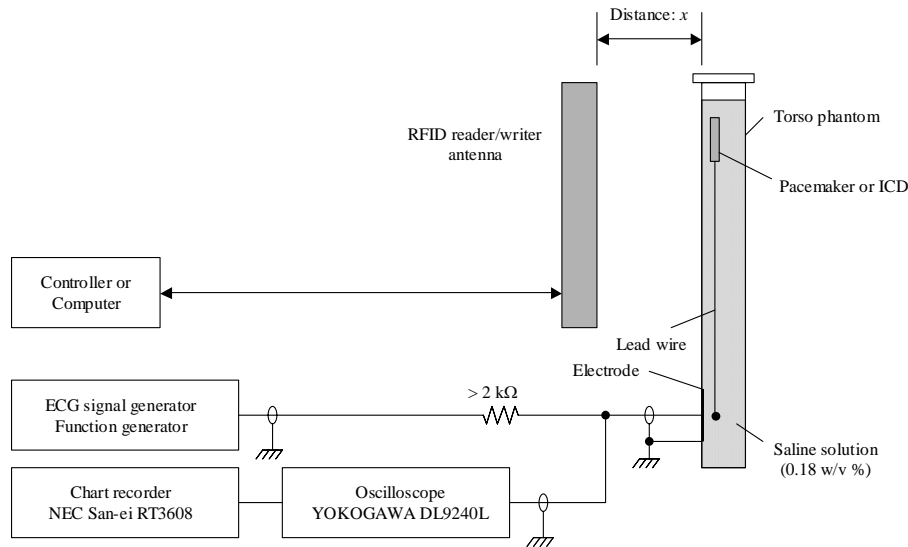

Fig. 1. Configuration of the test system.

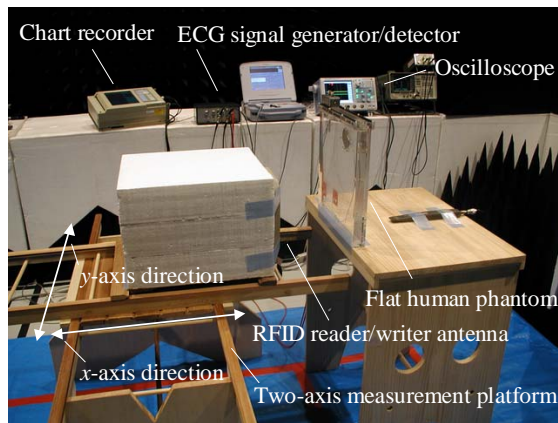

Fig. 2. Overall view of the in-vitro experimental system.

Fig. 3. The human torso phantom.

The in-vitro EMI test experiments procedure is explained as shown in Fig. 4. First of all, in order to obtain most conservative results, both sensitivity and refractory period of pacemakers and ICDs are programmed to maximum sensitivity and minimum time, respectively. Second, configurations of RFID reader/writers are prepared to actual operating mode. The next step depends on frequency bands of RFID reader/writer. EMI of 125 kHz and HF band are assumed to be caused by induced voltage, which follows Faraday's law of induction [4]. Malfunctions may happen when "an inductor coil" composed of lead wire of pacemakers and ICDs receive changing magnetic field radiated from RFID reader/writer antennas. Because of this mechanism, interferences are examined while the phantom is exposed to changing magnetic field. Antennas are moving in y-axis direction (as shown in Fig. 2) and closely attached to the torso phantom. EMI of UHF band and 2.45 GHz band occurs due to direct coupling between antennas and terminals of pacemakers and ICDs [4]. Interference is investigated while the antenna is located at a fixed position and closely attached to the torso phantom.

EXPERIMENTS TO ASSESS EFFECTS FOR PACEMAKER PATIENTS

Then, the ECG signal for each mode is recorded on the paper for 100 seconds. In addition, the distance between antennas and the torso phantom (x -axis direction in Fig. 3) is increased when interference occurs. In this case, the maximum interference distance (distance where EMI disappears) is found out and recorded in centimetres. As long as interference exists, sensitivity of pacemakers and ICDs are stepped down to five levels (maximum, 1.0 mV, 2.4 mV, 5.6 mV, minimum) and the maximum interference distance is also recorded. Breakdowns of the EMI test modes and settings are shown in Table 4.

Operating modes of pacemakers and ICDs are VVI mode (the Ventricle chamber is paced, the Ventricle chamber is sensed, and the response to sensing is Inhibited) and AAI mode (the Atrium chamber is paced, the Atrium chamber is sensed, and the response to sensing is Inhibited). In addition, unipolar and bipolar modes are chosen to their sensing/pacing polarity. For each of the operating modes, there are two types of EMI test modes are conducted - one with an injected ECG signal (typical inhibition), and one with no injected ECG signal (typical asynchronous pacing). With ICDs, there are two additional test modes. False Positive mode (one with no injected ECG signal and false detection of fibrillation), and False Negative mode (one with injected ECG signal and false non-detection of fibrillation) are investigated. The EMI test experiments are conducted in a closed, electromagnetic shielded anechoic chamber in Hokkaido University.

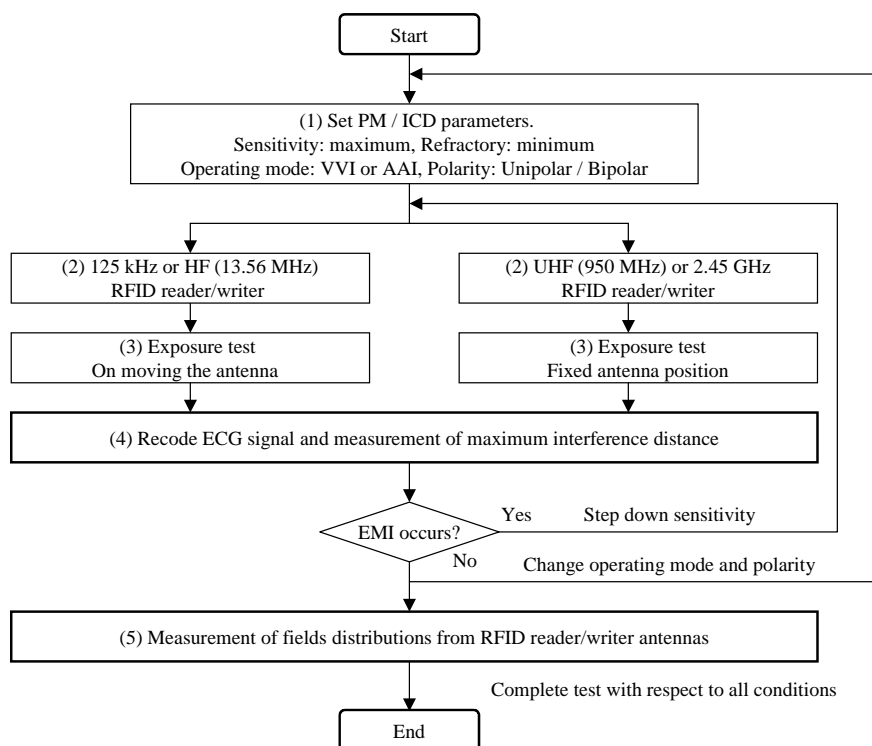

Fig. 4. In-vitro EMI test experiments procedure.

Table 4 EMI test modes and settings.

EMI test modes		Inhibit		Asynchronous		Inhibit		Asynchronous		False Positive	False Negative	Total Modes
PM/ICD Operating modes		VVI		VVI		AAI		AAI		AAI	AAI

Total modes		72	100	72	100	76	92	76	92	44	44	768

PM: Pacemaker, ICD: Implantable cardioverter-defibrillator

UNI: Unipolar, BI: Bipolar

Finally, measurements of field distributions described in the next section are carried out. The measurement area is determined based on the experimental results. In order to find out the correlation between obtained EMI data and field strength, precise measurement is required.

Field distribution measurements of RFID reader/writer

To obtain detailed data to clear up correlations between EMI and EMF strength, field distributions of RFID reader/writers antennas are measured. Both electric and magnetic fields are determined for all RFID reader/writers antennas shown in Table 3. The reason for this is a near field of the antennas is not proportioned to each other. For 125 kHz and HF band, measurement of 729 sample points which include $70\text{ cm} \times 70\text{ cm} \times 70\text{ cm}$ (width \times height \times depth) at 10 cm separation are carried out. In addition to this wide area measurement, we examined more fine separation for the depth direction (x -axis direction in Fig. 2). We measure 1029 sample points which include $70\text{ cm} \times 70\text{ cm} \times 20\text{ cm}$ (width \times height \times depth) at 1 cm separation for the depth direction. Figure 6 shows the probe positioners for low frequency bands, which is made of styrene foam. This positioner enables reliable measurement taking the advantages of low reflection or absorption of EMF. Electric field probe EMR-300 (Wandel & Goltermann GmbH, Germany) and magnetic field probe 11941A (Agilent technologies Inc., Palo Alto, CA, USA) are used. For the UHF band and 2.45 GHz, measurements of 3459 sample points are also performed. These measurements include the area of $36\text{ cm} \times 36\text{ cm} \times 20\text{ cm}$ (width \times height \times depth) at 3 cm separation for the width and height direction and at 1cm separation for the depth direction. Electric field probe IXP-050 (IndexSAR Ltd., Newdigate, England) and magnetic field probe 7405-903 (ETS-Lindgren, Cedar Park, TX, USA) are employed.

Figure 6 is a typical 3-dimensional magnetic field radiated from a HF band antenna. In addition, differences of field strength radiated from 4 types of 125 KHz antennas are shown in Fig. 7. This figure indicates 1-dimensional magnetic field strengths at the central axis of the antennas. Values of y -axis are normalized to the maximum field strength out of 4 types of antennas.

EXPERIMENTS TO ASSESS EFFECTS FOR PACEMAKER PATIENTS

Results & Discussions

First, results of the EMI test experiments are discussed. A total of 768 test modes are used in the experiments. As shown in Fig. 8, 107 modes are affected when pacemakers and ICDs are programmed to maximum sensitivity. Therefore the affected rate is about 14 %. Under these conditions, the maximum interference distance is 15cm. In addition, when the sensitivity is stepped down to minimum sensitivity, the affected mode and rate are 26 modes and about 3 %, respectively. The maximum interference distance of this sensitivity is 11 cm. From this EMI test experiment, when the radio wave from antennas are continuous wave or do not have time-varying envelope curve, no malfunctions happen on pacemakers and ICDs. On the other hand, if they are exposed to changing fields such as pulse modulated wave or changing magnetic field due to movement of antennas, probability of the EMI occurrence is much higher than another condition.

Affected modes (Cumulative) and maximum interference distance
depending on sensitivity of pacemakers and ICDs.

Summary

In this paper, to assess the EMF fields' exposure effect from RFID reader/writer antennas, field strengths which cause effects for these implantable devices operations were examined from experimental and measured results. First, EMI due to commercially available RFID reader/writers on pacemakers and ICDs were investigated using newly constructed in-vitro experimental test system. This system was based upon an Irnich's flat torso phantom. In vitro EMI test experiments on 10 types of RFID reader/writers and 13 types of implantable pacemakers and defibrillators were conducted. The frequency bands were 125 kHz, HF (13.56 MHz), UHF (950 MHz) and 2.45 GHz. Secondly, EMF distributions of RFID reader/writer antennas were measured in detail. Finally, results of EMI test experiments were introduced and characteristics of interferences were discussed.

The correlation between the EMI test experiments results and field strength radiated from RFID reader/writers are now being investigated in detail. Further results and discussions are shown in later.

Running Title: Effect of electric field on keratinocytes

Key words: NIR, growth differentiation, keratinocytes.

Abstract

Electrotherapy is a treatment method in which an electric stimulus is used to achieve physiological changes in the body.

The specific aim of the present work concerns the effectiveness of low frequency electric fields treatment to modify biochemical properties of human keratinocytes (HaCaT).

Cells exposed to a 7 Hz electric field for one hour (twice daily), showed by Scanning Microscopy modification in shape and morphology; these modifications were also associated to different actin distribution revealed by phalloidin fluorescence analysis.

Indirect immunofluorescence with fluorescent antibodies against involucrin and β catenin, both differentiation and adhesion markers, revealed an increase in involucrin and β catenin expression, supporting that exposure to electric field carries keratinocytes to an upper differentiation level.

Such study confirmed our previous observation and support the hypothesis that 7 Hz electric field, may modify cell biochemistry and interfere in differentiation and cellular adhesion of normal keratinocytes.

INTRODUCTION

In the last twenty years there has been an increasing interest to investigate the possible effect of extremely low frequency (ELF) electric and magnetic fields (Chiabreara 1985, Zhadin 2001) on human health. The experimental approach to the electromagnetic field (EMF) effects on living systems is complicated by various reported non linearities (intensity, frequency and time windows of the fields) and peculiarities (cell type, age, treatment) so that extrapolation or replications among laboratories can hardly be made. The possible mechanisms of the induced effects are still not known, although a number of theoretical models have been proposed (Glaser 1992, Liburdy 1992, Barnes 1996,). This may be partially due to the difficulties in demonstrating reproducible results.

The aim of the present work is to clarify the action's mechanism at cellular level of an electrotherapy procedure performed by an electro-medical device still in clinical use and so easily reproducible in each biophysical setting like frequency, intensity and exposure's time.

Moreover a second aim of this work is to validate the effectiveness of the current clinical application protocols.

This work concerns the effect of 7 Hz electric field exposure on morphological and biochemical properties of normal human keratinocytes.

Human skin and mucosa, majorly constituted of keratinocytes, are the most exposed cells to the impact with electromagnetic radiation.

Keratinocytes are so an ideal model to analyse the biological effects of non ionising electromagnetic field, because they are the first cells to which the energy associated to the radiation, will directly be transferred.

HaCaT are epithelial cell line, ideal to understand if a physical agent such as electric field exposure (7 Hz) can interfere with cell morphology, biochemistry and modulate keratinocytes differentiation.

Our results indicate that two ours exposure daily to 7 Hz electric field could be responsible to a different morphological and cytoskeletal assept on HaCaT, together with the increase in involucrin expression, suggesting that EMF takes such cells at an upper differentiation level.

This data strongly support the efficacy of 7 Hz therapy for the treatment of skin deseases as well as a co adjuvant in the therapy of undifferentiated deseasaes.

MATERIALS AND METHODS

Cell Cultures

Cells were grown in Serum Free Medium (GIBCO Laboratories, Scotland) supplemented with antibiotics (110 IU /ml of penicillin and 100 µg/ml of streptomycin) at 37 ± 0.3 °C, 5% CO₂, and sub-cultivated once a week at a 1:3 ratio.

Exposure System.

The flask containing cells were placed between two electrode and exposed twice daily for 1 hours to a 7 Hz electric field at 100mV in a cells incubator under controlled condition (37 °C and 5% CO₂).

As a control experiment other sample of the same cells was placed in the cell incubator with no field, in the same conditions of the exposed one.

No differences were detected between control and sham cells.

Immunofluorescence Assay

HaCaT cells were cultured in SFM medium, starting at a concentration of 6×10^5 /ml. Exposed cells were cultivated in the same conditions in the exposure system at 7 Hz electric field for 72 hours. Cells were washed, air dried, fixed in paraformaldeide 4% in PBS for 15 minutes and tested by indirect immunofluorescence for the presence of involucrin, β catenin. Antibody against involucrin (Sigma) was used at 1:100 dilution, anti β catenin (Calbiochem) at a 1:500 dilution. After 45 minutes incubation in primary antibody, the slides were washed three times with PBS, dried and stained with fluorescein –isothiocyanate-conjugated goat antiserum to human immunoglobulin G (Amersham) at a dilution of 1:200. After further incubation for 45 minutes the slides were washed and examined by fluorescence microscopy. Four different sets of experiments were performed.

Electrophoresis

SDS-polyacrylamide gel electrophoresis (SDS-Page) was carried out according to Laemmli, 1970 . After 72 hours exposure to electromagnetic fields, equal amount of cell proteins from control and exposed cells , measured by Lowry test, were loaded for each line, after lysis in sample buffer. The samples were boiled for 5 minutes . Electrophoresis was carried on 7.5% SDS polyacrilamide gel at 30 mA for about 2 hours. Gel was subsequently transferred on nitrocellulose membrane (Biorad) at 200 mA for 3 hours, and membrane, after blocking in 3% not dried fat milk for 1 hours at room temperature, was incubated with EGF receptor antibody (Sigma) at a dilution of 1:100 as suggested by manufacturer and revealed by ECL (Amersham).

Three different sets of experiments were performed.

RESULTS

Indirect Immunofluorescence microscopy of modulation of Involucrin, and β -Catenin expression after exposure at 7 Hz electric field

The effect of EMF exposure on HaCaT cell expression of differentiation (Involucrin) and adhesion (β Catenin) markers is respectively reported in Tab and Fig. 1.

Exposed HaCaT cells showed an apparent increase in cells becoming positive to involucrin expression after field exposure compared to control cells. The increase in Involucrin positivity can suggests that 7 Hz HaCaT exposed cells were driven to an upper differentiation level.

As reported for the involucrin experiment also β Catenin seems to be more evident in cells after fiels exposure. The amount of cells positive to β Catenin and involucrine by indirect immunofluorescence is reported in Tab.1

The increase in β Catenin positivity in 7 Hz electric field exposed HaCaT cells, indicates a major cellular adhesion capacity compared to control cells.

Western blot analysis of both involucrin and β Catenin after 7 Hz exposure is reported in Fig. 1. The amount in both proteins seems to be affected by the treatment with the electric field.

DISCUSSION

In the last two decades, reports of biological effects of low-energy EMF have been increasing (Adey 1993, Pilla 1992, Hinsenkamp 1997). Particularly debated is the question of the epidemiological evidence (14) of adverse effects of an extremely low frequency magnetic field (ELF) generated by 50-60 Hz high voltage power transmission lines, video display terminals, electric blankets and other home appliances, which raise the possibility of deleterious health effects (Adey 1981) from exposure to radio frequency (Tenforde 1995) or low frequency fields (Savitz 1987). A valid objection is that field intensity is many orders of magnitude below the noise threshold so that selective, cooperative, or amplifying mechanisms must be postulated. There are also problems of reproducibility of reported effects. The therapeutic potential of ELF can be seen in the proven efficacy of low-energy, pulsed magnetic fields in non-union bone fracture healing (Weaver 1990), confirming that under certain conditions non-ionising electromagnetic energy can influence physiological processes in organisms (Kaiser 1988). Physiological paradigms for ELF effects are required. Clues may be found in the mechanisms by which ELF interacts with cultured cells under controlled laboratory conditions and by correlating in vivo evidence with in vitro data (Glaser 1992). Low frequency magnetic fields at 50 or 60 Hz are also reported to stimulate nerve regeneration (Phillips 1992) or alter gene transcription. They may also play a synergic role in cellular processes that are already activated, such as cell proliferation (Walleczek 1992). The role of Ca^{2+} in the transduction of these effects has been suggested, and indirect evidence of its involvement has been shown (Karabachtsian 1994).

In our work we analysed the effect of 7Hz ELF therapy on human epithelial cell line (HaCaT). Epithelial cells are an interesting model to study the biological effect of the interaction with non-ionising radiations, are not shielded by any other stratum of cells in the impact with electromagnetic radiation, and so they are totally available to the field.

Human keratinocytes cells are also a very good model to investigate the epithelial switch between proliferation and differentiation (Medema 1994).

The effect of 7 Hz exposure on HaCaT cells by ultra microscopy (data not shown), at cells confluency showed a modified morphological aspect: they are bigger and more elongated than controls. Exposed cells lost filopodia, and show a higher number of lamellipodia, specialized structures for cell-cell contact. The augment of cell-cell contact junctions, is also supported by the different distribution in β -Catenin as reported in and Tab.1.

β -Catenin is a protein implicated in cell-cell-adhesion, binding cytoplasmic domain of cadherin, and in signal transduction (Szabo 2001, Vasioukin 2001).

Cell adhesion molecules and their association with actin cytoskeleton play an important role not only in the maintenance of tissue integrity, but also in proliferation and differentiation.

Exposure to the field also causes rearranging of actin filaments (data not shown), leading to an increase in actin expression and in formation of stress fibres that cross parallel to the elongated cells.

Since modification of cellular growth rate and gap junction number with the consequent cytoskeleton rearrangement are implicated in cells transformation (Hsu 2000) we analysed the expression of involucrin as a differentiation marker of keratinocytes (Batta 2000). In human epidermis, involucrin is first observed in the cytoplasm of spinous and granular layer cells. In transition cells, it is equally distributed between the cytoplasm and the nascent corneified envelope, while in the corneocytes it is largely corneified envelope associated. In our experiments involucrin and especially β catenin expression in the exposed cells, is increased compared to control. (Fig .1). Since involucrin is a keratinization-associated molecules our observation may suggest that the exposed cells are at an upper differentiation level than controls..

This is a very important point suggesting a possible application of electrotherapy in the therapy of skin proliferative diseases. It would be very interesting, for example, to analyse the possibility of using electrotherapy as non invasive chemoterapeutic agent. Other authors have just reported therapeutical effects of electromagnetic radiation for clinical aims (Basset 1993, Leszczynski 2001, Pletnev 2000).

In summary, 7Hz electric field induces an alteration of growth and differentiation pattern on HaCaT cells. The modification of morphology, cytoskeletal aspect, and expression of adhesion and differentiation markers confirm our previous data that exposed cells are at an upper differentiation level.

Our results strongly suggests the possibility to use physical agents such as electric or electromagnetic field, in support to chemotherapy to fight epithelial proliferation diseases, as well as all the diseases in which cells are characterized to a lower differentiation state

STATIC MAGNETS AND PC6 CELLS: DIFFERENTIATION AND PROLIFERATION

Amanda B. Spence and Betty F. Sisken

Dept. of Biological Sciences and Center for Biomedical Engineering, University of Kentucky, Lexington, KY 40506

The objective of this study was to assess the effects of static magnetic fields on proliferation and differentiation of PC6 cells. Proliferation was measured by counting the number of cells in four different quadrants of each well in a 6-well plate after 2 days of incubation. Differentiation was assessed in the same wells by measuring the percentage of cells with neurites (cell extensions) growing from the cell bodies.

We used two Tectonic ceramic magnets (800 Gauss surface field strength, 4 cm in diameter) one under a well at each end of the plate and exposed the cells for three hours /day for each of 2 days . Culture plates were placed directly on the surface of the two magnets. Nerve growth factor (NGF) in phosphate buffered saline (PBS) or PBS alone was added to the cultures; the final concentration of NGF tested was 10 and 20 ng/ml.

A significant effect on differentiation ($p=0.0215$) was found when comparing cultures treated with either concentration of NGF and cultures treated with PBS. The presence of a static magnetic field had no additive effect with the NGF nor did it have any effect alone. Growth, in terms of number of cells, was not affected by the magnetic field + PBS, NGF alone, or NGF + magnetic field.

We also asked the question whether the magnetic fields had any direct effect on the culture media alone or with the addition of PBS or NGF. Therefore, the culture media (+PBS or +NGF) was exposed to the magnetic fields for 3 hours and then the PC 6 cells were added. After 2 days of incubation the results demonstrated that the fields did not affect NGF action since cell differentiation was still increased to the same extent over PBS controls, and no differences were found in growth (proliferation) assessments.

These results are can be compared and contrasted to those found when we tested 2 Hz pulsed electromagnetic fields (PEMF) on PC6 cells, where neurite outgrowth was inhibited (Shah et al, 2001) and with 15 Hz PEMF where differentiation of dissociated sensory neurons was inhibited (Webb et al, 1994). In contrast, we described a stimulation of neurite outgrowth from explants of chick sensory ganglia (Sisken et al, 2000) using the same 800 gauss static magnetic field + NGF. The mechanisms underlying these effects are not known, but may involve magnetic field regulation of NGF activity. Since this dose of magnetic fields may be outside the biological window for single cells, future studie will be run in which the magnetic fields are reduced in strength.

EFFECTS OF GSM-900 JAMMER'S ELECTROMAGNETIC FIELD ON HUMAN ELECTROENCEPHALOGRAM

Abstract

Widespread use of mobile phones and the necessity for restriction of it in some places have increased the growth of mobile phone jammer (MPJ). The MPJ produces an electromagnetic field (EMF) that blocks the mobile phone communications. It generates noisy signals at a frequency in order of the mobile phone. People, who exposed to the MPJ field, usually are unaware about its effects on their health. So, at this study the influences of mobile phone jammer's exposures on human electroencephalogram (EEG) are evaluated experimentally.

Thirty healthy participants attended two sessions, one week apart. In experimental and sham session, before exposure, 19 Channels EEG signal was recorded with closed eyes. In experimental session, they exposed to the MPJ's EMF for twenty minutes. In sham session, MPJ was turned off. Then, in two sessions, EEG signal was recorded twenty minutes after beginning of each session. The follow-up EEG signal was recorded at fortieth minutes. Then, power spectrum of EEG signals was calculated using Matlab toolbox.

The analysis of results showed that area under power spectrum curve off EEG signals in some channels has changed between sham and exposure session. The frequency parameters of EEG signals have been changed due to the MPJ exposures, especially in the alpha and theta band of frequency domain. We concluded that this radiofrequency exposure could affect the participant's awareness

Keywords: Electromagnetic Field, Mobile Phone Jammer, GSM 900MHz, EEG

Introduction

Widespread use of mobile phones and the necessity for restriction of it in some places have increased the growth of mobile phone jammer (MPJ). The MPJ produces an electromagnetic field (EMF) that blocks the mobile phone communications. GSM use 900MHz EMF as a carrier for communications. But MPJs generate noisy signals at a frequency in order of the mobile phone. Therefore in study of MPJ's effects we can refer to researches of mobile phone effects. Should be noted that MPJs just used for produce noise and may be have other deferent frequencies that defer between company's products and their noise production methods.

The first cell phone jammer was marketed in 1998 after Goldshtein. MPJs are used in some places that mobile phone usage is forbidden such as exams or in places that quite is necessary, for example banks, mosques, churches, theaters and meetings. Furthermore People may be resident long time near MPJ, for example in offices or prisons. Operation of these devices is illegal or very limited in some countries and discussions about its usage continue [1]. These discussions are on two subjects; MPJs usage limits mobile benefits essentially in emergency situations, and probable health hazard of MPJ's EMF [2].

On the other hand, some people that think mobile phone ring and their families and friend's irregular call is ruining their rest and Security and has contrast with their relationship with another people, interest to use low power MPJs and try to make this a manner [3].

People, who exposed to the MPJ field, usually are unaware about its effects on their health. So it's necessary to validate the effect of MPJ on human health.

Generally EMF effects can be divided in to thermal and non-thermal effects. More Standards are based on released heat from EMF that SAR (specific energy absorption rate) is famous standard. But in order weak Electric field that emitted from mobile phone and MPJs non-thermal effects is more probable [4].

Non-thermal effects of EMF that often has been considered are effect on carcinogenic processes, tumor growth, etc. until now Scientific can't find any exact relationship between Mobile phone or MPJ usage and human physiology and pathology. Among researches effect on brain and nervous system has been considered, specially.

Some of probable effects of EMF on nervous system are effect on function of neural membrane, calcium efflux, neuronal excitability, neurotransmitter systems, thermoregulatory behavior, Motor activity, auditory responses, learning and memory, blood–brain barrier and finally effect on brain activity such as EEG and ERP [5].

EEG is an immediate reflection of change in function of nervous system that make it considerable. The effect of EMF on brain activity has been studied later in number of experiments. Studies often report EMF exposure of mobile phone increase spectral power of resting EEG, especially in alpha band [6,7,8,9,10,11,12] but in another research didn't observe such changes [13,14,15].

In some experiment spectral power of Sleep EEG increased due to EMF exposure of mobile phone [10,16,17,18,19,20,21,22] and in another studies didn't result these effects [23,24,25,26].

About effects of mobile phone exposure on EPs some researches have been done. Some of this research report changes in measured parameters [7,9,26,27,28,29,30,31,32] and in another studies can't observed any changes [33,34,35,36].

At this study the influences of mobile phone jammer's exposures on human resting electroencephalogram (EEG) are evaluated experimentally.

Materials and methods

Subjects

Thirty healthy males aged between 18 and 27 years participate in the study. Participants often had university degrees and easily have been described about purpose and procedures of the study. Before participate in experiment any participant was introduced with experimental tools and situation.

Participant were asked about any nerves illness and difficulties such as long term headache, sleep disorder etc. also in first session of experiment an EEG with clinical order has been recorded and a neural specialist reviewed this record and finally sample with neural difficulty has been forgave from experiment and invited for more clinical exam. During the experiment two peoples were invited for clinical difficulty investigating exams.

Before first session participants have been noted that had sufficient sleep and didn't use sleepy and neural drugs. Before experiment any participant wrote an informed consent that contained detail of study.

Procedure

Participants attended two sessions, one week apart, for experimental and sham session. In each session participant seat on a comfortable armchair and an expert technician placed the electrodes on his head. Before exposure, 19 Channels EEG signal was recorded with closed eyes. In experimental session, they exposed to the MPJ EMF for twenty minutes from right side. In sham session, MPJ was turned off and participants were unaware that MPJs was on or off. In two sessions, EEG signal was recorded twenty minutes after beginning of each session. The follow-up EEG signal was recorded at fortieth minutes. The experimental protocol is shown in table 1.

Table 1: experimental protocol

Session	30 s EEG Recording	20 min being near the MPJ	30 s EEG Recording	20 min after Second record	30 s EEG Recording
First	Background	ON Exposure / OFF	After	Follow-up time	Follow-up
Second		OFF Exposure / ON			

EMF exposure

GSM 900 use 890-960 MHz EMF as a carrier for communications. This wide band divided to two bands, uplink band 890-915 MHz, and downlink band 935-960 MHz. downlink is the transmission path from a Base Station to the Cell Phone. Uplink is the transmission path from a mobile station to the base station [37].

MPJs emit EMF similar to downlink (935-960 MHz) but with ramp modulation, which block mobile communications around itself. MPJs emit EMF similar to carrier of GSM, but in a stable frequency band and with constant power for a long time. These make MPJ a suitable EMF generator for our study.

EMF emitter that has been used in our study was MPJ 101 (Moje Nasr Gostar co.) that emits noisy 935-960 MHz EMF with power of 1 W and can block GSM900 communications in a 15 meters circle. Fig 1

Frequency of EMF that emitted form MPJ 101 was tested with a Spectrum Analyzer (TR4131) that has correct frequency band

Fig 1: MPJ 101

MPJ 101 has an 8 cm, quarter wavelength antenna. Participants sat approximately 50 cm apart the MPJ. It can be assumed that participants placed in far field of antenna. Therefore power density on volunteer head can be estimated:

$$\frac{I}{S} = \frac{I}{4\pi r^2} = \frac{1}{4\pi(0.5)^2} \left(\frac{W}{m^2} \right) = 0.32 \text{ Wm}^{-2}$$

Public standard level for power spectrum that ICNIRP determined in 935 MHz is 4.68 Wm^{-2} . It can be seen that power spectrum is smaller than standard level.

Data acquisition

EEG was recorded using a 19 Channels EEG recording system (sholeh danesh co.). It has an 8-bit A/D card and its sampling rate is 250 Hz. 19 Ag-AgCl Saline Pad Electrodes placed on participant's head using 10-20 system and fixed with a head cap strap. Two earlobe electrodes were hanged to ears with ear clip as reference and recording was performed with monopole montage.

Data acquisition, Preview and primary analysis performed using SD-C24 EEG software that install on recording PC. Default mode of recording system that performed for clinical application has a 35 Hz low pass

and a 1 Hz high pass filter. We were using this mode for clinical exam of participants that has been said before. For experimental record a 70 Hz low pass and a 0.3 Hz high pass filter were used.

More than 30 s EEG with closed eye was recorded in any record (background, after and follow-up) that has been said before.

Data analyzes

Recording data was saved in special file format. This primary format has been converted to a data array with Matlab software format (MathWorks, Inc. version 7) that can be analyzed in Matlab toolboxes. The MAT file after convert has been reviewed with eeglab4.515 toolbox [38] and compared with printed records to validate conversion program.

Recorded EEG was reviewed with eeglab4.515 toolbox and in any record (background, after and follow-up), 10 without movement artifact 1 s windows have been selected.

Frequency analysis has been done in the Matlab. FFT (Fast Fourier Transform) was performed on each 1 s data to calculate power spectrum. Because frequency contents of normal adult lie between 0.1-40Hz [39] in power spectrum calculation we abandoned upper than 45 Hz contents. We also abandoned frequency content lower than 1Hz because our frequency resolution in power spectrum calculation. Then Relative Power Spectrum (RPS) has been calculated as below.

$$\text{RPS} = \text{Area under Power Spectrum curve of any rhythm} / \text{Total area under Power Spectrum curve}$$

Fig 2: Original EEG wave ,Voltage as a function of time (first), Power Spectrum (second) and RPS (third)

Then power spectrum has been averaged in 10 second. For evaluation of changes in EEG rhythms, RPS has been summed in each rhythm. EEG rhythms have been determined as shown below

Delta	δ	1-3 Hz	Beta	β	14-35 Hz
Theta	θ	4-7 Hz	Gamma	γ	36-45 Hz
Alpha	α	8-13 Hz			

Essentially EEG RPS may change as a function of time during each session. For finding any effect of EMF exposure, recording data during the real exposure with that recorded in sham session should be compared. In each session, Growth Ratio (GR) from background to after, from after to follow-up and from background to follow-up records were calculated as below.

$$\text{GR} = (\text{after RPS} - \text{background RPS}) / \text{background RPS} \dots$$

Therefore we could compare between two sessions with three GRs.

Statistical analyses

Statistical analyses were performed with SPSS (SPSS Inc. version 11.5.) software Paired T-test was performed for GR of RPS between two sessions. Differences were considered statistically significant at $P < 0.05$. Paired T-test was performed for each 19 electrodes in all rhythms separately.

For Paired T-test the data should be normal. Therefore normality of data was checked in One-Sample Kolmogorov-Smirnov Test. If normality test failed nonparametric test (Wilcoxon signed rank test) would use.

Additionally for evaluation the inherent changes of EEG rhythms due to time, Repeated measures have been performed on background, after and follow-up records in each session separately. Mauchly's Test of Sphericity Were performed before Repeated measures tests. If Mauchly's Test of Sphericity failed, other methods (Greenhouse-Geisser, Huynh-Feldt and Lower-bound) would perform.

Result

Repeated measures of data showed changes in EEG rhythm due to time especially in Theta and Alpha rhythms. Analyze of differences showed significant changes in GR from background RPS to after, between two sessions in some electrode and in some rhythms. As be shown in Table 2. Positive sign in the table shows increase in RPS change in those rhythm and negative sign show decrease in it. It seems that immediately after exposure the natural changes of EEG rhythms were modified. Slow brain potentials increased due to exposure. Analyze of GR from follow-up to after record also showed more differences between sham and experimental sessions as shown in Table 3. Comparing sham and experimental records showed decrease in GR in Theta rhythms. Result of comparing GR from follow-up to background record showed less change in two sessions (Table 4).

Discussion

Our result showed RPS of slow brain potential increased immediately after exposure in some electrode, it is inconsistent with result of more experiment that have reported increase in alpha rhythm due to exposure. It may be result of large widespread data in upper rhythms that unable us to see significant differences.

Comparing GR from follow-up to after record in sham and experimental records showed decrease in natural changes in Theta rhythms.

Results showed increase in GR from background to after record and decrease from after to follow-up record in Theta rhythm due to EMF exposure that is reasonable.

Analogizing GR from background to follow-up record in two sessions showed partially increase in beta rhythm that perhaps it happens accidentally.

In our study the frequency parameters of EEG signals have been changed due to the MPJ exposures, especially in the alpha and theta band of frequency domain. We concluded that this radiofrequency exposure could affect the frequency content of EEG and participant's awareness.

Abstract

Wavelet analysis has proven a useful tool for time-frequency analysis of EEG and Event Related Potential (ERP) signals. Moreover the effect of electromagnetic fields (EMFs) on brain activity is an important issue that requires further investigation.

The present study focused on the temporal analysis of the early components of ERPs stimulated by sounds of different frequencies (low=500 Hz and high=3000Hz), using wavelets. The ERPs were recorded at 16 scalp electrodes during a working memory test with and without electromagnetic radiation (900 MHz). The sample included 10 women and 9 men. Temporal comparisons were made between the energies, averaged at the time intervals before and after the P50 amplitude peak (30-80 msec after warning stimulus onset).

Results showed that the maximum energy variability was observed for the α -band at the C4 electrode. In the absence of radiation men exhibited a significant increase after the P50 peak of the energy for the low frequency stimulus, while women exhibited this significant increase for the high frequency stimulus. Conversely the presence of radiation seemed to suppress this energy increase for both sexes with the exception of women for the low tone.

Introduction

Since the advent of GSM-based cellular phone networks general concerns have been raised regarding potential health effects of high frequency electromagnetic fields (EMF). The close proximity of a mobile phone to the user's head leads to the absorption of part of the EMF energy in the head and the brain [1]. This is especially important in view of the observation that the shape of the head is oval, with a short axis of 15 – 17 cm in length, which is half the wavelength of the 900MHz transmission signals of the cellular phones. Consequently, the head may serve as a lossy resonator absorbing much of the energy emitted by cellular phones [2]. The above considerations necessitate the study of the possible effects of EMF on brain and behavior [3].

Analysis of EEG signals proved a useful and appropriate approach in measuring the level and spatial distribution of cortical activation during cognitive task performance. Several reports provide evidence that the exposure to EMFs increases the cortical activity as it is reflected in the increase of spectral power in the alpha band of the EEG signal. [4, 5, 6, 7]. However, there are reports which do not confirm these results [8].

The event-related brain potentials (ERPs) consist of a series of positive and negative peaks of the brain signals occurring at a fixed time relative to an event. These component peaks are studied with the assumption that they index meaningful aspects of cognitive processing [9]. Specifically the earlier components of the ERPs (0 – 100 msec after stimulus) are thought to represent the activity of the sensory pathways that transmit the signal generated at peripheral receptors to central processing systems.

There have been several studies of mobile phone emissions on the brain activity using the sensory components of ERPs methodology with various results [10, 11, 12, 13, 14 and 15]. It should be noted that the early components are 'modality specific', that is they are influenced primarily by the stimulus parameters such as intensity and frequency [16]. Our team recently found that the MP-EMF affect the patterns of the auditory P50 component of ERPs (generally 30-80 msec post-stimulus)[17]. In particular the amplitude of P50 evoked by low frequency stimuli at Fp1 and O1 electrode is statistically significant increased in the presence of MP-EMFs. In contrast the exposure to MP-EMFs revealed statistically significant decrease of the amplitude of P50 evoked by high frequency stimuli, at Fp1 electrode as compared to themselves without MP-EMF exposure. These findings have been conceived as evidence that the MP-EMF emitted by mobile phone affect pre-attentive information processing reflected by the synchronized responses of the thalamocortical system of the P50 component of ERPs. [18, 19]

Moreover, having in mind that EEG and ERP data sets are nonstationary a useful tool to analyze these signals in both time and frequency domain is the Wavelet Analysis. Many studies have used wavelets in order to explore EEG and ERP waveform structure. Rosso and Figliola [20] used the wavelet transformation at generalized epileptic tonic/clonic EEG signals and showed that the Relative Wavelet Energy describes accurately the epileptic recruitment rhythm. Samar et al. applied wavelets at data collected from a sample consisted of controls and alcoholics in order to compare ERP values at different frequency levels [21]. They found significant group differences at the theta band at the span of P300 and also at the alpha band for the P100-N100-P200-N200. However, up to our knowledge, there are no studies specifically examining the effect of EMFs on ERPs using wavelets.

On the other hand the gender-dependent brain function is a subject under research. In a study about sex differences in resting EEG activity it was reported that EEG power for females was greater than the EEG power for males, with significant differences observed for delta, theta and beta bands, but not for the alpha band [22]. These findings concur with the results of a study of Briere et al. where women were found to have higher EEG power values at the central, parietal and left temporal electrodes [23]. Only one study has so far investigated EEG gender-related differences under exposure to mobile phone EMFs [24]. The subjects' EEG was recorded during the anticipatory period of performance on an auditory Wechsler test for 500 ms, either under real (900 MHz CW with a mean power at 0.64 W) or sham exposure. The amount of baseline EEG spectral energy of males was greater than that of females, while EMF exposure decreased the EEG energy of males and increased that of females. The above findings indicate that it is necessary to examine the possible impact of EMFs on brain activity separately for males and females in order to avoid the confounding effects of gender.

In summing up, cortical activation during the early components of the ERP signal is thought to be gender, modality and frequency specific. In view of the above considerations, the wavelet analysis of energy changes at the time intervals before and after the P50 could be of value in identifying possible pathophysiological alterations evoked by EMFs. Thus, the present study was designed to determine the time dependence of the effect of EMF exposure on the energy of early components of ERP during a working memory test.

Methods

Participants

Nineteen healthy individuals (9 men and 10 women, mean age = 23.3 ± 2.23 years, mean education = 16.9 ± 1.82 years) participated in the experiment. The male and female subgroups were homogeneous with regards to age and educational level. All participants were right-handed and had no history of any hearing problem. Informed consent was obtained from all subjects.

Experimental setup and Measurement Procedure

The subjects were evaluated with the digit span Wechsler Auditory test [25]. A warning stimulus of either high “(3000 Hz)” or low frequency “(500 Hz)” was presented through earphones to the subjects, who were asked to memorize the numbers that followed. The warning stimulus lasted 100msec. A one second interval followed the onset of the warning stimulus and then the numbers to be memorized were presented by a male voice. At the end of the number sequence presentation, the same signal tone was repeated. If the frequency of the signal tone was low the subjects had to recall the numbers in the same order as that presented, else, if the frequency was high, the subjects had to recall the numbers in the opposite order. Before any ERPs’ recording, practice trials were administered until the subjects could clearly discriminate the warning stimuli (tones). After completion of the above-mentioned process, i.e. the practice trials, a rest period of five minutes followed, before the recording of the ERPs.

The experimental setup included a Faraday room, which screened any electromagnetic interference that could affect the measurements. The subjects sat in an anatomical chair and a certified dipole antenna was fixed near their right ear. The dipole’s model was ELECTRO-METRICS EM6924 and the antenna factor was 27.4dB/m at 900MHz. Care was taken so that the distance between telephone and ear (about 20 cm) was constant during the whole session. The antenna was driven by a signal generator, which could be switched on or off. In the on mode the antenna emitted a 900 MHz electromagnetic field with mean power at 64 mWatt. [24] The signal was not modulated. The field strength was 3V/m at the point where the subjects’ head was standing.

ERPs were recorded during 1.1 sec between the onset of the warning stimulus and the onset of the first administered number. The electrophysiological signals were recorded with Ag/AgCl electrodes. Electrode resistance was kept constantly below 5 k Ω . EEG activity was recorded from 15 scalp electrodes based on the International 10-20 system of Electroencephalography [26], referred to both earlobes. An electrode placed on the subject’s forehead served as ground. The bandwidth of the amplifiers was set at 0.05 Hz to 35Hz. During the administration of stimuli, the subjects had their eyes closed in order to minimize eye movements and blinks. Eye movements were recorded through electro-oculogram (EOG) and recordings with EEG higher than 75mV were rejected. Warning stimuli, as well as learning material, i.e. the numbers to recall, were presented binaurally via earphones at an intensity of 65dB sound pressure level. The earphones did not have metal components in order to avoid EMF concentration. The evoked biopotential signal was submitted to an analogue-to-digital conversion, at a sampling rate of 1 KHz. Each recording session consisted of 52 repetitions of the trial.

The subjects performed the task twice, with (on mode) and without (off mode) radiation, with an interval of two weeks between the measurements. The order in which the subject was exposed at the EMF (exposure at the first or second visit) was random.

Because the P50 component is included in the array of early-endogenous ERPs components, which normally are modality specific, the ERPs induced by the two modal stimuli were averaged separately [16]. In particular, two varieties of P50 waveforms were obtained, one (low P50) evoked by the low frequency modality (26 trials) for each lead in all subjects and another (high P50) evoked by the high frequency modality (26 trials) for each lead in all subjects .

Wavelet Analysis

The Discrete Waveform Transform (DWT) was applied at the collected ERP data. The DWT analyzes the signal at different frequency bands with different resolutions by decomposing the signal into a coarse approximation and detail information. DWT employs two sets of functions, called scaling functions and wavelet functions, which are associated with low pass and high pass filters, respectively. The decomposition of the signal into different frequency bands is simply obtained by successive high pass and low pass filtering of the time domain signal. The original signal is first passed through a half band high pass filter and a low pass filter. After the filtering, half of the samples can be eliminated according to the Nyquist’s rule, since now the highest frequency of the signal is half of this before filtering. The signal can therefore be subsampled by 2, simply by

discarding every other sample. This constitutes one level of decomposition. The “mother” wavelet function that was used to our analysis was Daubechies 1 (db1) and the levels of decomposition were seven.

This decomposition halves the time resolution since only half the number of samples now characterizes the entire signal. However, this operation doubles the frequency resolution, since the frequency band of the signal now spans only half the previous frequency band, effectively reducing the uncertainty in the frequency by half. At every level, the filtering and subsampling will result in half the number of samples (and hence half the time resolution) and half the frequency band spanned (and hence doubles the frequency resolution). The ERP data of the experiment consisted of 1000 values for each channel for each person after the averaging. In order to obtain high frequency resolution in δ band, the 1000 value sample was artificially subsampled. That is, the average of each 8 successive measurements of the signal was calculated the and consequently, 125 values were formed to which the Wavelet transform (WT) was applied.

The second step of the analysis was the reconstruction of the signal (or in our case the reconstruction of the details of the signal), that is how its components can be assembled back into the original signal without loss of information. The details of the signal at each level j are given by the function

$$D_j(t) = \sum_{k \in \mathbb{Z}} C_{j,k} \psi_{j,k}(t)$$

where $\psi_{j,k}$ is the mother wavelet and $C_{j,k}$ are the wavelet coefficients which were calculated at the previous step. The wavelet coefficients $C_{j,k}$ can be interpreted as the local residual error between successive signal approximations at scales $j-1$ and j . $D_j(t)$ is the residual signal at scale j . It contains the information of the signal at frequencies $2^{j-1}f_s \leq |f| \leq 2^j f_s$.

Then the energy at each resolution level $j=1, \dots, 7$ and at each instant, was calculated. This is the energy of the reconstructed detail signal:

$$E_j(t) = |D_j(t)|^2$$

The energies of the last three levels ($E_5(t), E_6(t), E_7(t)$) were summed up so that the sum stands for the energy at the time domain of the delta band (frequency 1-4 Hz). Each one of the remaining four levels with descending order represents the energy of the basic EEG rhythms theta, alpha, beta and gamma respectively.

The total energy at each time was calculated as follows:

$$E_{tot}(t) = \sum_{j=1}^N E_j(t)$$

The accuracy of the results was confirmed by comparing them with those derived from previous analysis with the FFT [24].

Finally the energy at each band was evaluated on a temporal basis. This means that the energies, were averaged at the time intervals before and after the P50 amplitude peak (30-80 msec after warning stimulus onset) and comparisons were made between these energies (before – after P50).

Statistical analysis

The parameter under consideration is the energy calculated with the Wavelet Transform. Preliminary statistical analysis was carried out independently for each modality (high, low) and for each frequency band (delta, theta, alpha, beta and gamma). The energies at the 15 leads were subjected to three way MANOVA with radiation (on – off), gender (male – female) and time interval (before – after the P50 peak) as the three independent factors. When the MANOVA procedure revealed statistical significance, the energies before and after the P50 peak were subjected to multiple pairwise comparisons for each lead, gender and radiation condition independently. Statistical significance was set at the 0.05 level.

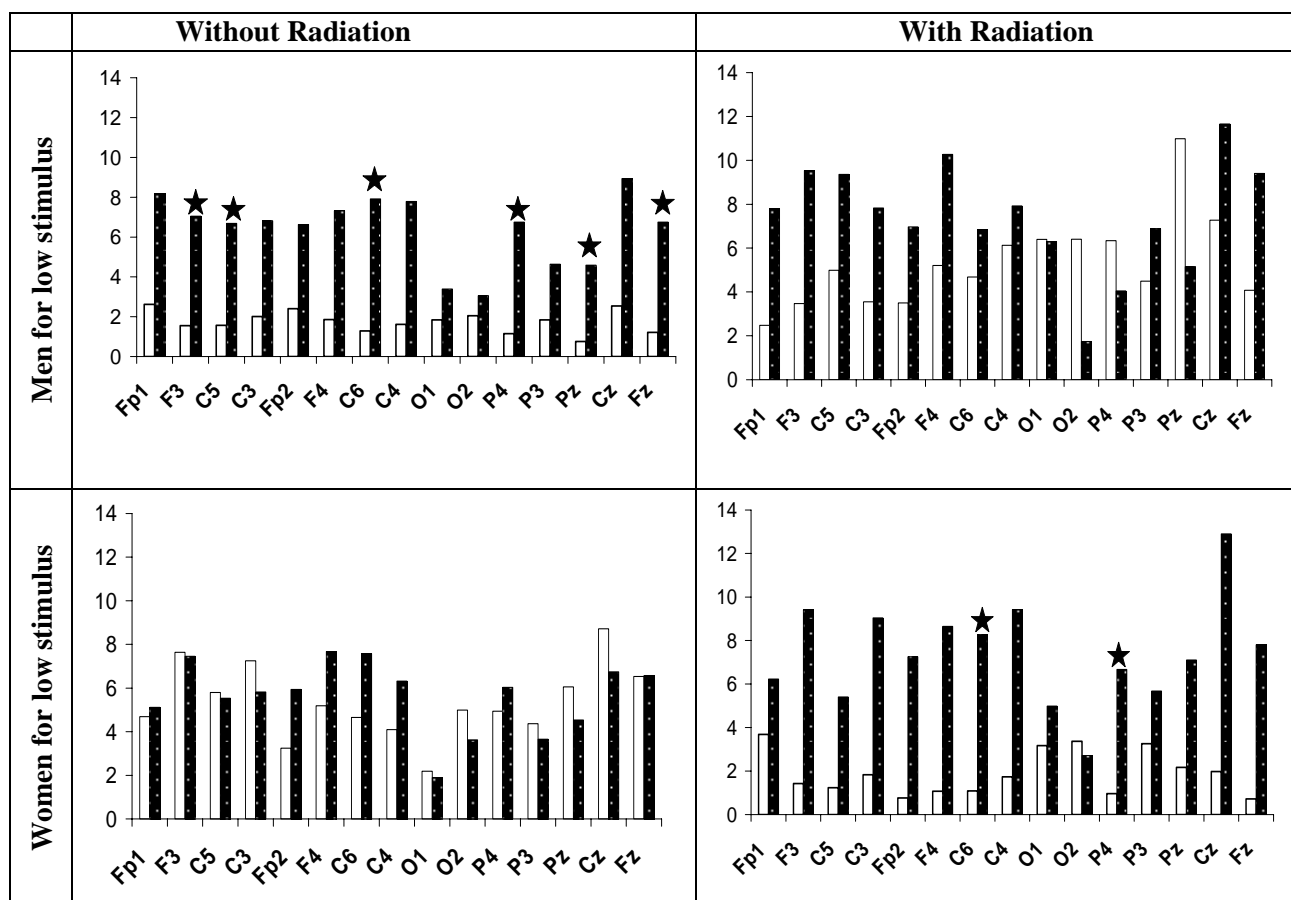

Results

The MANOVA procedure revealed that significant energy differences were found only at the alpha frequency band. Figure 1 displays the energies before and after the P50 component and Table 1 displays the energy differences after – before the P50 component for tones, genders and EMF conditions. . In Figure 1 asterisks indicate the electrodes for which the energy differences are statistically significant. It seems that these temporal energy differences are mostly positive and highly dependent on the interaction among modality, gender and EMF. In the absence of radiation men witnessed a significant increase of the energy of the alpha frequency band

for the low stimulus at electrodes F3,C5,C6,P3,Pz and Fz, while women evidenced the same increase for the high stimulus at electrodes F3,Fp2,F4,C6 and C4. The presence of radiation seems to suppress this temporal energy increase with the exception of women for the low tone at electrodes C6 and P4.

Discussion

The main objective of this study was the investigation of the influence of EMF on the sensory components of ERPs (within, 100msec after warning stimulus onset) elicited during a WM task. In order to retain both time and frequency domain information of ERPs we used the Wavelet analysis. Utilizing the two key aspects of Wavelet analysis-its multiresolution nature and its adaptivity to nonstationarity in ERP data elicited during a WM task- temporal comparisons between the energies, averaged at the time intervals before and after the P50 amplitude peak (30-80 msec after warning stimulus onset) were made.

The most robust findings were observed in alpha-frequency band activities. In particular in the absence of radiation, comparing the energies of the alpha frequency band before and after the P50 component, men exhibited a significant increase for the low stimulus at electrodes F3,C5,C6,P3,Pz and Fz, while women evidenced the same increase for the high stimulus at electrodes F3,Fp2,F4,C6 and C4. The importance of the obtained results may be explained, considering the activation of 'alpha system', using the so called conventional ways of EEG variables (power-, amplitudes-, network connection measures and phase delays). When a subject is stimulated (e.g. auditory stimulus) the flow of information is accompanied by alpha enhancement involving structures in the auditory pathways (e.g. reticular formation, medial geniculate nucleus, thalamus, hippocampus and the auditory cortex). [27]

Neurophysiological studies underscore that the alpha-band of evoked potentials is strongly correlated

with sensory function (e.g. thalamo-cortical circuits associated with working memory and probably with long – term memory engrams) [28]. It was also suggested that the alpha-band activity reflects a cortical –deactivation (the augmentation of attention-demanding mental activity is associated with decrease of alpha rhythm) [29]. In the light of these theories, the stimulus-related increase of the energy (before and after the P50), mostly for the alpha activity, which was found here, could though speculative, point to the possibility that the underlying neural networks of pre-attentive operation needs to be deactivated (relaxed) when the process of attention is ongoing. Conventionally the waveform of P50 which (as noted earlier) reflects pre-attentive operations is followed by the N100 waveform which represents the process of attention [16].

A second striking finding was the effect of gender on the patterns of energy changes within the time-window of the sensory components of ERPs for the alpha frequency. Gender has been shown to influence a variety of electrophysiological measures. However, the factors that mediate gender-related electrophysiological differences are not well understood. One possible mechanism which has been postulated is that steroid hormones estrogens and testosterone might be related to the neural oscillations associated with thalamocortical circuits which underlie alpha band activity [30]. Within this context, in order to understand better the observed gender-related differences concerning the two warning stimuli (high- vs low-warning tone) which evoked the measured ERPs, it seems reasonable to keep in mind that the auditory pathways from cochlear nucleus to the auditory cortex exhibit tonotopic organization during the ontogenesis.[31] In the light of these theoretical assumptions , it could be speculated that males and females have different neural networks activities involved in the transfer of information in thalamo-cortical circuits. This is in line with neurophysiological studies indicating that during the adolescence in males the volume of white matter increases faster than in females. [32]

Moreover, the observed increase of the energy, before - after the P50 amplitude peak, points to an increased cortical activation as a direct consequence of EMF exposure. Such an effect may be due either to the psychophysics effect of the EMF exposure on brain tissue and/ or to its neurophysiological consequences (e.g. influence on blood brain barrier and/or thermal alterations). In relation to the neurophysiological point of view recent studies provide evidence, indicating the involvement of blood brain barrier (BBB) permeability, in the effect of mobile phones on the brain [33]. For instance it has been shown that EMF radiation has the potency to significantly open the BBB in a way that not only small but also large molecules, including toxic ones, can pass the BBB producing neuronal damage in the cortex, hippocampus and basal ganglia of rats exposed to EMF radiation for two (2) hours [34, 35]. On the other hand the EMF radiation is associated with enhancement of the temperature of the underlying tissues of the brain. It has been reported local heating (estimated to 0.11°C rise in brain) due to radiation of EMF [36]. Interestingly, psychophysiological and neurophysiological studies have provided a direct relationship between alpha EEG activity regarding both thermal stimulations of the brain and changes of BBB. For example EEG coherence in alpha band significantly decreased in human subjects during tonic thermal stimulation [37]. Within this context, a brain imaging study by Korn et al., 2005 [38] using single photon emission computed tomography (SPECT) and addressing to both cortical- and BBB function in patients with postconcussion syndrome found significantly lower power in the alpha band compared with matched controls in conjunction with BBB disruption. Therefore, the changes described regarding the alpha EEG activity would seem to indicate adverse effects of EMF upon brain operation, which possibly may be mediated through the thermal and BBB alterations induced by EMF radiation.

In summary, the present study is an attempt to find sensory ERPs correlates associated with possible effects on human brain after exposure to EMFs. In order to retain both time and frequency domain information of ERPs we used the Wavelet analysis. Temporal comparisons between the energies, averaged at the time intervals before and after the P50 amplitude peak (30-80 msec after warning stimulus onset) were made. It was found that only for the alpha band the energy was mostly increased and this change is highly dependent on the interaction among modality, gender and EMF exposure.

Abstract

The preliminary experiments were carried out on the group of depression patients (women, 18 subjects) and comparison group of healthy volunteers exposed during 30 min to 450 MHz microwave radiation modulated with 1000 Hz frequency. The field power density at the scalp was 0.9 mW/cm². As a subjective criteria of depression mood, the Brief Affect Scale (BAS) and Visual Analogue Scale (VAS) before and after each exposure procedure was used. Parallel a ratio of the EEG power in symmetric EEG channels of the different brain hemispheres FP1/FP2, T3/T4, P3/P4 and O1/O2 was evaluated. Statistical analysis of these parameters for individuals with post-hoc Bonferroni correction was applied.

The BAS revealed mood improvement after exposure for majority of depressive subjects (11) and no changes for others (7). The VAS detected significant improvement in subjective mood score after exposure. The EEG analysis showed the biggest difference in symmetry between hemispheres in temporal area. Average values are higher in higher EEG rhythms. The difference was significant in 3 cases of exposed and in 5 cases of sham recordings. Significant results in sham condition indicate that the parameter selected as a measure is not very steady among depressive patients. This makes difficult to detect the effect caused by the EMF exposure.

Keywords: EMF effect, depression, Brief Affect Scale, EEG analysis, symmetry of brain hemispheres.

Introduction

Clinical treatment approaches for depression disorder utilize primarily pharmacologic agents, antipsychotic and antidepressant drugs, that sometimes are of limited efficacy and may have objectionable side effects. ECT is usually effective as a treatment for depressive disorder, but it involves general anesthesia and some degree of memory loss, and its effects can be transient. Repetitive transcranial magnetic stimulation (rTMS), initially developed to test gross central nervous system function, more recently has been applied with some success in the treatment of depression [1–3]. The success of rTMS in the treatment of depression has been varied and has been described in a recent review as “often statistically significant (but) below the threshold of clinical usefulness” [1]. rTMS treatment can be unpleasant, with some patients declining participation due to scalp pain induced by the apparatus [4]. There is also a small risk of seizure [5].

Recent report has suggested mood improvement in patients with bipolar disorder immediately after they underwent an echo-planar magnetic resonance spectroscopic imaging (EP-MRSI) procedure that can be performed within clinical MR system limits [6]. The mood states of subjects in an ongoing EP-MRSI study of bipolar disorder were assessed by using the Brief Affect Scale, a structured mood rating scale, immediately before and after an EP-MRSI session. The characteristics of the electric fields generated by the EP-MRSI scan were analyzed. Mood improvement was reported by 23 of 30 bipolar disorder subjects who received the actual EP-MRSI examination, by three of 10 bipolar disorder subjects who received sham EP-MRSI, and by four of 14 healthy comparison subjects who received actual EP-MRSI. Significant differences in mood improvement were found between the bipolar disorder subjects who received actual EP-MRSI and those who received sham EP-MRSI. The electric fields generated by the EP-MRSI scan were smaller (0.7 V/m) than fields used in repetitive transcranial magnetic stimulation (rTMS) treatment of depression (1–500 V/m) and also extended uniformly throughout the head, unlike the highly nonuniform fields used in rTMS. The EP-MRSI waveform, a 1-kHz train of monophasic trapezoidal gradient pulses, differed from that used in rTMS. These preliminary data suggest that the EP-MRSI scan induces electric fields that are associated with reported mood improvement in subjects with bipolar disorder. The findings are similar to those for rTMS depression treatments, although the waveform used in EP-MRSI differs from that used in rTMS.

The findings reported above allowed expecting EMF effect on depression at the field power density much lower than used in TMS. In our previous studies the effect of the modulated 450 MHz microwave radiation on human EEG has been detected at the EMF level 0.16 mW/cm^2 , lower than the recommended health protection limit [7–10]. In majority of modulation frequencies and EEG rhythms the exposure increases the EEG energy level and variability. Has such stimulation any effect on depression?

The aim of this study is to investigate the effect of modulated microwave exposure to the state of depression. In the study we tested the hypothesis that the modulated with 1000 Hz frequency 450 MHz EMF has an effect on subjects with depressive disorder. Distinction of reactions to microwave exposure will be performed by 1) clinical rating utilising psychiatric tests 2) EEG analysis.

Method and equipment

Subjects

The experiments were carried out on two groups of volunteers: a group of patients with major depressive disorder and a group of healthy comparison subjects. The group of subjects consisted of 18 persons, mean age 39 years, standard deviation 10 years.

The study was conducted in accordance with the Declaration of Helsinki and has formally approved by the local Medical Research Ethics Committee. All risks, benefits and possible adverse events associated with EMF study participation were explained to subjects, who provided written informed consent before entering the study.

Subjects with major depressive disorder were selected from hospital inpatient unit. Subjects with non-psychotic major depressive disorder as defined by ICD-10 criteria and determined by 17-item Hamilton Depression Rating Scale (HAM-D) score more than 14 were eligible. The average HAM-D score for the group was 21 (SD 3.3). Subjects were without antidepressant treatment, only regular (same dosage for more than 3 weeks) benzodiazepine use was allowed. Concomitant treatments for current general medical conditions were permitted on the basis of clinical judgment (patients receiving medication with known CNS side effects were not eligible).

All the subjects passed two experimental procedures - with exposure and sham. During each test session, the succession of exposure-sham was randomly assigned. Only one experimental EEG recording was performed for a subject during a day between time interval 9 a.m. to noon. The subjects were not informed of their exposure, however, they were aware of the possibility of being exposed.

Subjects were asked to evaluate Becks Depression Inventory (BDI) and Visual Analogue Scale (VAS) before and after each EMF procedure (both exposure and sham). Subjects were also asked to evaluate Brief Affect Scale (BAS) after each EMF procedure.

Microwave exposure

The 450 MHz microwave radiation was generated by the Rhode & Swartz (Germany) signal generator model SML02. The RF signal was 100% amplitude modulated by the pulse modulator SML-B3 at 1000 Hz frequency (duty cycle 50%). The generator signal was amplified with the Dage Corporation (USA) power amplifier model MSD-2597601 and additional laboratory amplifier (Miteq-Eesti, Estonia). The generator and amplifier were carefully shielded and located in the laboratory room. The 10W EMF output power was guided by a coaxial to the quarter-wave antenna NMT450 RA3206 by Allgon Mobile Communication AB, Sweden, located at 10 cm from skin from the left side of the head.

The spatial distribution of the microwave power density was measured by the Fieldmeter C.A 43 Chauvin Arnoux (France) field strength meter. The calibration curves of the field power density dependence on the distance from the radiating antenna were obtained from these measurements performed in the real condition of the experiment. During the experiments, the stability of the microwave level was monitored by the IC Engineering (USA) Digi Field C field strength meter. Estimated by the measured calibration curves, the field power density at the skin from the left side of the head was 0.9 mW/cm^2 . The spatial distribution of the field density around the head and upper torso was not uniform: Digi Field C field strength meter indicated maximum level of $0.9 \pm 0.1 \text{ mW/cm}^2$ at the left side of the head, minimum level of $0.14 \pm 0.05 \text{ mW/cm}^2$ at the right side of the head and $0.45 \pm 0.05 \text{ mW/cm}^2$ above the head. Measured field power density was $0.8 \pm 0.15 \text{ mW/cm}^2$ at 10 cm distant from the left ear, near and the left shoulder and $0.17 \pm 0.05 \text{ mW/cm}^2$ near the right shoulder. The SAR value, calculated based on the maximum field power density, is 2 W/kg .

Experimental procedure and EEG recording equipment

The study consisted of two experimental procedures identical for all subjects. The first protocol included continuous EEG recording during 30 minutes. The 450 MHz 1000 Hz modulated microwave exposure is switched on during all recording. The second protocol is the same except that the microwave exposure is switched off.

The experimenter and the subjects were in the same laboratory room during the experiments. The room was dark but no other special conditions were provided. The subjects were lying in a relaxed position, eyes closed and ears blocked during the experiments.

The Cadwell Easy II EEG measurement equipment was used for the EEG recordings. The EEG was recorded using 32 electrodes, which were placed on the subject's head according to the international 10-20-electrode position classification system. The channels for analysis were chosen to cover the entire head: frontal - FP1, FP2; parietal P5, P4, temporal - T3, T4; occipital O1, O2 and the reference electrode Cz. The EEG recordings were stored on a computer with a 400 Hz sampling frequency. The recorded EEG signals were observed by an experienced neurologist. The artifacts were detected by visual inspection. The recordings containing multiple artifacts were removed and the recording was repeated.

Afterwards, off-line data processing was executed. The energies of the five basic EEG rhythm frequencies (delta, theta, alpha, beta and beta2) were extracted from the total EEG signal (0.5 - 48 Hz) by filtering.

Clinical evaluations

Each subject completed the Visual Analogue Scale (VAS) and the Brief Affect Scale (BAS) based on their subjective feeling and symptoms before and/or after every experimental procedure.

Visual Analogue Scale (VAS) was introduced for subject self-evaluation of mood. VAS is 100-millimeter line with one end matching mood “very bad” and second end matching as “very good”. Subject has to determine visually her mood on the day of evaluation marking this on the line. In our study subjects evaluated VAS on the day before and the day after EMS procedure (both exposure and sham). This allows to determine immediate effect as scale can be to be applied every day. The lengths of the lines from beginning up to the marker were manually measured afterwards (results from 0 to 100 are possible). The lower numeric results in VAS show more depressive mood. VAS was introduced to determine immediate effect of EMS, as HAMD and BDI are designed for longer period (minimum 1 week).

The Brief Affect Scale was applied to the study after the experimental protocols. The subjects were asked to fill out the form and answer how much, if any, their feeling had improved or worsened since the time before experimental protocol. The subjects provided their responses on a 7-point scale, as follows: 3, very much improved; 2, much improved; 1, minimally improved; 0, no change; -1, minimally worse; -2, much worse; and -3, very much worse. These numerically ranked responses were grouped into the categories of improved (3 to 1), same (0), and worse (-1 to -3) for statistical treatment. This grouping is referred to as the Brief Affect Scale ratings.

The two-tailed paired Student t-test was used to estimate differences between exposed and sham exposed results for depressive and healthy subjects. All p values lower than 0.05 were considered as significant.

EEG analysis

The dynamics of the EEG energy of the theta (4-8 Hz), alpha (8-13 Hz), beta1 (13-20 Hz) and beta2 (20-40 Hz) rhythms frequencies was analyzed.

Assymetry between left and right brain hemisphere EEG channels was selected as a measure for estimation of the effect. The ratio of the power spectral density of the signals for the symmetric channels FP2/FP1, T4/T3, P4/P3, O2/O1 from right and left hemispheres was calculated and analysed.

The power spectral density (PSD) was estimated by means of Welch's averaged periodogram method. The signal was divided into overlapping sections (50%), with the length of 2048 points and windowed by the Hanning window. Afterwards, the power on the theta, alpha, or beta band W_m was computed for each subject (indexed by $n \in [1, 18]$) and hemisphere (indexed by $m=1, 2$) as the area under the spectrum for the corresponding frequency band (integral of the band).

The relative misbalances of the PSD in symmetric channels were selected for further analysis. Finally, parameter A for a subject was calculated as follows:

$$A = (W_{1n} / W_{2n} - 1) * 100 \%,$$

where W_{1n} and W_{2n} were the power spectral densities of the right and left symmetric channel respectively.

The average values and standard deviations of parameter A for different EEG channels pairs for the individual subjects and for the whole group were calculated.

Statistical analysis was performed for the differences between exposed and sham exposed recordings. For sham recordings, normal physiological processes determine the asymmetry between hemispheres and the standard deviation σ for the parameter A was calculated.

According to the “zero hypothesis”, the EEG recordings of subjects under microwave exposure cannot be distinguished from sham signals. Thus, the “zero hypothesis” implies that and

$\langle (W_1 - W_2)^2 \rangle = \langle (\tilde{W}_1 - \tilde{W}_2)^2 \rangle$. Consequently, if the “zero hypothesis” is true, the quantity

$x = (W_{1n} - W_{2n})^2 \sigma^{-2}$ is a f -distributed random quantity, the cumulative distribution of which is routinely designated as $F_{1,15}(x)$; the indices 1 and 18 stand for the numbers of the degrees of freedom.

Accordingly, the ratio of the computed power difference to the standard deviation (calculated on the basis of sham signals) of the differences can be used as a quantitative measure, showing how well the “zero hypothesis” is satisfied, respective p -values are obtained by means of the cumulative f -distribution:

$$p = F_{1,15} \left[(W_{1n} - W_{2n})^2 \sigma^{-2} \right].$$

Post-hoc mean comparisons were tested by Bonferroni approach with a 0.05 confidence level.

Signal processing and calculation of parameters were performed in the LabVIEW and MatLab programming and signal processing environment.

Results

The results of psychiatric tests are presented in Table 1. Most of the depressive subjects reported improvement of her mood after exposure (11). This number is less for sham procedure (7). Numbers of the subjects with no changes of mood is less for exposed subjects (7) and higher for sham subjects (10). Only one subject reported worsening of her mood during sham procedure.

The changes in mood during procedure are quite well reflected in score of the BAS test: average score for exposed procedure is 0.81 and sham procedure 0.62.

VAS test revealed significant change between scores before (average 33.3) and after (average 40.2) for exposed subjects and no significant change for sham exposed subjects.

These results are in good agreement with the study [6], where mainly the Brief Affect Scale was used for evaluation of the mood improvement in bipolar depression. Anyway, such results may be caused by the factors different from EMF as inconveniences related to MRI equipment or EEG cap.

Table 1. Data of the Brief Affect Scale (BAS) and Visual Analogue Scale (VAS) tests for depressive subjects

	Total number of subjects	Sub. Reporting improvement	Sub. Reporting worsening	Sub. Reporting no change	BAS		VAS			
					Mean for group	SD	Before		After	
							Mean for group	SD	Mean for group	SD
Depression subjects exposed	18	11	0	7	0.81	0.75	33.34	17.97	40.21	25.18
							$p=0.04$			
Depression subjects sham exposed	18	7	1	10	0.62	1.20	35.68	19.46	40.29	21.21
							$p=0.25$			

Data of the EEG analysis are presented in Figures 1 and 2. Figure 1 presents the average values of A for different frequency bands, for control group in sham (1a) and EMF condition (1b). As can be seen, those values behave quite similarly. The biggest difference seems to be in frontal region. However, trends in different channels are the same in sham and EMF condition.

As expected, for control group, there were no significant results in the ratio of the computed power difference to the standard deviation of differences (calculated on the basis of sham signals) in the case of sham recordings nor recordings under the influence of EMF.

Figure 2 presents the average values of A for different frequency bands, for depressive group in sham (2a) and EMF condition (2b). The results are not as similar between two EMF conditions as they were in control group. The biggest difference occurs in temporal area. Average values are higher in higher EEG rhythms, however having opposite signs. Beta rhythms are more influenced also in frontal area. Trends in other brain regions are mostly the same in sham and EMF conditions.

MODULATED MICROWAVE EFFECT ON DEPRESSION

In the case of EMF recordings of depressed patients, the ratio of the computed power difference to the standard deviation of differences (calculated on the basis of sham signals) was significant in 3 cases, and in the case of sham recordings in 5 cases. Significant results in sham condition indicate that parameter *A* is not very steady among depressive patients. This makes difficult to detect which deviation of the parameter is caused by EMF.

Figure 1. The average asymmetry of hemispheres (average values of *A*) for different EEG rhythms for control group in EMF (1a) and sham (1b) condition.

To investigate the behaviour of parameter *A* with depression, the depressive patients' sham recordings were compared with the sham recordings of the control group.

Now, the ratio of the computed power difference to the standard deviation of differences (calculated on the basis of sham signals) for control group sham recordings was zero and depressive group sham recordings had 7 significant results. The influence was highest in frontal theta rhythm 16.7% and the depression slightly influenced also the beta1 and beta2 rhythms in frontal and temporal region (5.6%).

Figure 2. The average asymmetry of hemispheres (average values of A) for different EEG rhythms for the group of patients with major depressive disorder in EMF (2a) and sham (2b) condition.

Summary

The BAS revealed mood improvement after microwave exposure for majority of depressive subjects (11) and no changes for others (7). The VAS detected significant improvement in subjective mood score after exposure. These results support the recent promising research where mood improvement in bipolar depression by low-frequency magnetic field has been reported [6].

The EEG analysis based on evaluation of symmetry between brain hemispheres detected the biggest difference related to EMF exposure in temporal area. Average values are higher in higher EEG rhythms. But the difference related to EMF was significant in 3 cases, and in the case of sham recordings in 5 cases. Significant results in sham condition indicate that the parameter selected as measure is not very steady among depressive patients and makes difficult to detect which deviation of the parameter is caused by EMF exposure.

The preliminary results are promising and the further investigation should be aimed to finding a better measure for EEG analysis and performing experiments on larger number of subjects.

Abstract

The aim of this study was to investigate the effects of a 0.5 T static magnetic field (SMF) of a MRI clinical unit on TNF- α release from peripheral blood mononuclear cells (PBMC) obtained from patients with rheumatoid arthritis (RA). These patients didn't take biological drugs, as receptor TNF- α or anti-TNF- α monoclonal antibodies, at the time of collecting samples. PBMC were isolated and cultured in complete medium and split into 2 groups of samples, one to be exposed and the other one as control. After 2 hrs of exposure to the SMF at 37°C, cells were stimulated or non stimulated with a mitogen, and incubated for 48 hrs. After the incubation the supernatants were collected and assayed by ELISA technique for TNF- α production. The results demonstrated a significant decrease of TNF- α release in PBMC of patients with RA exposed to 0.5 T SMF. RA is a multisystem disorder. It predominantly causes inflammation in synovial joints and tendon sheaths and results in suppressed erythropoiesis, but can also lead to serositis, alveolitis, ocular scleritis, subcutaneous nodules and hepatosplenomegaly. The positive clinical response to drug therapy with TNF- α -neutralizing agents shows that the inflammation is largely TNF- α dependent, at least in the synovium.

Introduction

Static magnetic field (SMF) produces different bioeffects on cells of the human immune system. A strong SMF is commonly employed by magnetic resonance devices in clinical practice to obtain tomographic images of the whole body (MRI, magnetic resonance imaging). Immune system cells represent a well known and sensitive model for the study of magnetic field bioeffects [1-3]. We have previously demonstrated that the SMF generated by a 0.5 T superconducting MRI clinical unit causes *in vitro* alteration on cytokine release in human peripheral blood mononuclear cells (PBMC) from healthy volunteers [1, 3]. Among these cytokines, it was observed a decreased release of TNF- α in exposed cells [4, 5]. TNF- α is a regulator of the immune response, playing an important role in several inflammatory conditions, such as rheumatoid arthritis (RA) [6, 7]. Some papers have dealt the effects of electromagnetic fields (emf) as a potential therapy in the treatment of arthritis [8, 9]. The aim of this study was to investigate the effects of a 0.5 T SMF of a MRI clinical unit on TNF- α release from PBMC obtained from patients with rheumatoid arthritis (RA).

Materials and methods

PBMC of 4 patients affected by RA and that didn't take biological drugs, as receptor TNF- α or anti-TNF- α monoclonal antibodies, at the time of collecting samples, were used for the experiment. PBMC were isolated from heparinized blood by centrifugation on Ficoll-Hypaque (Pharmacia, Uppsala, Sweden). Cells were maintained in RPMI-1640 (Gibco, Grand Island, NY) supplemented with 10% heat-inactivated pooled human AB⁺ serum, 2 mM L-glutamine, 20 mM HEPES, 100 U/ml penicillin, 100 μ g/ml streptomycin, 5 x 10⁻⁵ M 2-mercaptoethanol and 150 IU/ml rIL-2. PBMC were split into two groups of samples, one to be exposed and the other one as control to be kept under isothermal conditions for the whole time of the experiment. After 2 hrs of exposure to the SMF, cells were stimulated with a mitogen, lipopolysaccharide (LPS), employed at a 0.5 μ g/ml suboptimal concentration. After 48 hrs of culture supernatants were collected and stored at -70° C until tested. TNF- α content was assessed using immunoenzymatic methods. The commercial enzyme-linked immunosorbent assay (ELISA) was reagent set human TNF- α (EUROCLONE, Devon, UK). A superconducting MRI unit (Vectra; GE Medical Systems, Milwaukee, WI, USA) commonly employed for clinical examinations was the source of the 0.5 T SMF. A specific device for keeping the cell samples at 37° C was used; it was constituted

EFFECTS OF THE 0.5 T SMF OF A MRI UNIT ON TNF- α RELEASE OF HUMAN PBMC FROM PATIENTS WITH RHEUMATOID ARTHRITIS

by a thermostated water bath in which a plexiglass tube holder, with the tubes containing cell samples, was placed before its introduction within the gantry of the MRI unit.

Results

After 48 hrs of *in vitro* culture, a significant decrease of TNF- α release was observed in PBMC of 4 patients affected by RA exposed for 2 hrs to a 0.5 T SMF, stimulated or not stimulated with LPS, in comparison with sham-exposed cells (Fig. 1).

Discussion

It has been previously observed that exposure of human PBMC from healthy volunteers for 2 hrs at 37 °C to the 0.5 T SMF of a MRI clinical unit caused a decreased release of cytokines in exposed cell [1, 3]. It was also demonstrated a decreased release of TNF- α in human macrophages under the same condition of exposure [4]. A related decrease of intracellular free calcium -whose compartmentalization through cell membrane is a part of the cell response mechanism to magnetic fields and inhibits activation of immune system cells- was also found in the exposed macrophages [5]. In this study the effects of a 0.5 T SMF of a MRI clinical unit on TNF- α release from PBMC obtained from patients with RA was evaluated. RA is a chronic inflammatory disease affecting 1% of the population [6]. TNF- α is a cytokine that promotes the inflammation and its associated with fever and signs (pain, tenderness, and swelling) in several inflammatory conditions, including RA [6, 7]. Some drugs have been introduced that, blocking the action of TNF- α , reduce the signs and symptoms of inflammation and stops the progression of joint damage [10]. Moreover, TNF- α is now recognized as a critical cytokine orchestrating differentiation and proliferation, as well as the ability to induce cell death [6]. TNF- α has been implicated as the causative agent in a number of pathologies, including cachexia, septic shock, rheumatoid arthritis, autoimmunity, and induction of HIV expression. Activated T cells, macrophages, and other non-lymphoid cells produce TNF- α . In RA, the antibodies (IgM) produced react with connective tissue components such as collagen and proteoglycans as well as with determinants in the Fc region of IgG and form IgG-IgM complexes, which get deposited in the joints and activate complement cascade [11]. This mechanism leads to erosion of cartilage and bone. The existing treatments available for RA cannot be considered as curative or definitive therapy. Hence, alternative and safe therapy regulating signaling pathways is absolutely essential. There is an increasing interest in the therapeutic use of emfs in arthritis, stimulated in large part by recent advances in alternative and complementary medicine [8, 9]. In this paper, after 48 hrs of *in vitro* culture, a significant decrease of TNF- α release was observed in PBMC of patients affected by RA exposed for 2 hrs to the 0.5 T SMF of a MRI clinical unit. Although these preliminary results, obtained from PBMC of only 4 patients affected by RA, need to be confirmed on wider population, this work may supply a key to the comprehension of mechanisms responsible of the therapeutic effects of emfs in arthritis. Interesting perspectives in the use of emfs as an adjuvant or alternative form of therapy in arthritis may furthermore develop.

Overview of ISO TC215 Technical Report #21730: "Health informatics - Use of mobile wireless communication and computing technology in healthcare facilities - Recommendations for electromagnetic compatibility with medical devices

Joseph J Morrissey

Motorola Labs, 8000 West Sunrise Blvd, Ft. Lauderdale, FL 33322

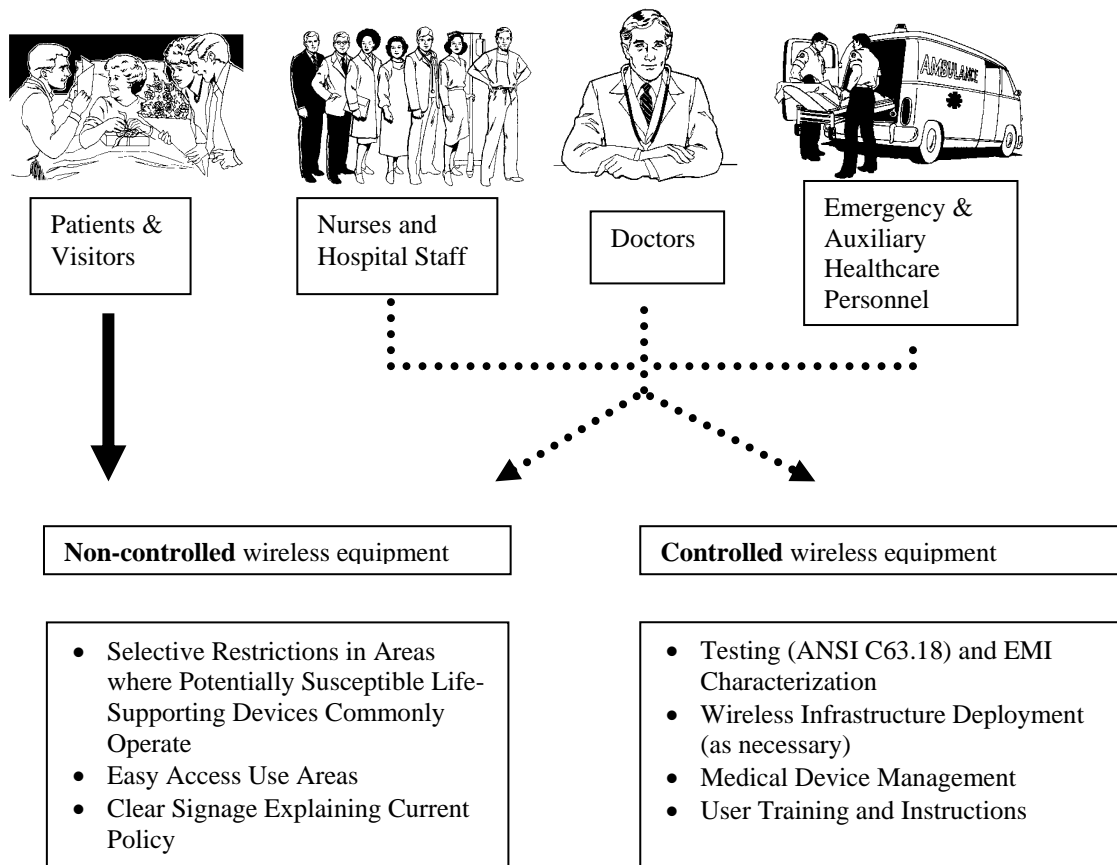

Abstract: Worldwide, healthcare facilities are recognizing the need to incorporate new technology and provide better point-of-care information to improve healthcare delivery, while reducing medical errors. Computing technologies, electronic medical record systems, and seamless access to information using wireless communication can offer significant advancements to healthcare communication and health informatics exchange. Such wireless technologies include the use of mobile phones, handheld computers / PDAs, WiFi / 802.11.x local area networks, personal area networks including 802.15.1 (Bluetooth) / 802.15.4 (Zigbee) / WiMedia / UWB Alliance (UWB), two-way pagers, radios, etc. In addition, visitors and patients are also finding use of personal mobile phones and other wireless devices increasingly valuable, especially in times of crisis. Previously, no uniform international guideline existed for the appropriate deployment, use, and management of mobile wireless communication and computing technology within healthcare facilities to mitigate potential electromagnetic interference (EMI) with medical devices. At one extreme, overly-restrictive policies in some healthcare facilities may inadvertently act as obstacles to the deployment of beneficial technology. At the other extreme, unmanaged use of mobile wireless handsets in healthcare facilities can place patients at risk. An equally important factor in this issue is that healthcare organizations throughout the world have a variety of different resources, needs, concerns, and RF environments that may not all be addressed by implementation of a single prescriptive management strategy. The current Technical Report offers balanced guidance to allow diverse healthcare organizations realize the benefits of mobile wireless technology while also providing necessary and sufficient safeguards against undesired and unintended risks of EMI.

Introduction: The non-controlled/unmanaged use of mobile wireless equipment by individuals visiting or working in healthcare facilities has steadily increased, regardless of existing healthcare policy. However, published reports suggest that the level of risk for accidental EMI events from government and other non-profit health agency sources appears to be relatively small, although underreporting of such events may be substantial. Anecdotal observations of suspected EMI events or incidents with ECG and EEG machines, apnoea monitors, ventilators and radiant warmers, infusion pumps, wheelchairs, and other devices have been reported or referred to in a number of publications [1]-[15]. Ad hoc test studies [16]-[28] have confirmed that EM interference effects can be caused by certain wireless transmitters in susceptible medical devices, although this generally requires specific conditions (transmission at higher power levels, close proximity, for extended periods of time) that may not be common during normal use.

Although the recently approved second edition of the IEC International Standard 60601-1-2 specifies general immunity levels of 3 V/m for medical equipment and systems that are not life-supporting and 10 V/m for life-supporting medical equipment and systems, manufacturers in the US and many other countries are allowed to justify lower levels and there is no consistent international regulation enforcing this standard. Many mobile wireless handsets exceed the 3 and 10 V/m limits when operating at maximum power and in close proximity. Further, older medical devices still in use may not have been constructed or tested to the same EM immunity level. Despite the potentially serious level of risk due to unmanaged mobile wireless handset use, most mobile wireless equipment might be allowed to operate, even where potentially susceptible medical devices are used, if comprehensive management procedures are implemented.

Recommendations: The following recommendations are intended to help the healthcare facility achieve a reasonable assurance of EMC with their medical devices while allowing for the deployment of wireless RF technology. These recommendations are built on the foundations from the AAMI TIR 18-1997, recommendations from the AMA Council on Scientific Affairs, the American Society for Healthcare Engineers,

and several other publications and reports. In general, the healthcare facility should create a management, testing, procurement, and education program and policies addressing electromagnetic compatibility with active medical devices and the deployment of wireless technology. Because of the wide range of wireless technology involved, there are specific recommendations dealing with both the wireless emitters that are controlled or managed by the healthcare facility and wireless emitters that are not easily controlled by the facility (e.g., patient or visitor PDAs, computers, or cellular telephones). The following flow chart illustrates basic steps outlined in the specific recommendations to develop a facility strategy allowing wireless equipment to operate without unnecessary restrictions while at the same time sufficiently managing and mitigating potential EMI issues.

Important recommendations are made equally to Medical Device Manufacturers, Healthcare facilities, and Wireless Equipment Manufacturers.

Risk management of medical devices is covered in ISO 14971. All medical devices (including systems of medical devices such as would be formed with wired or wireless communication devices) should meet that standard and be managed to take into account compliance with ISO 14971 over the life cycle of the device. For Medical Device Manufacturers, they should continue to meet and exceed current IEC 60601-1-2 [33] listed electromagnetic immunity levels in the design of new medical equipment. Medical devices that are not directly covered by this technical report should also be designed, manufactured, and deployed using the appropriate consensus standards with respect to EMC. (e.g., active implanted devices [55], in vitro diagnostics [56]). It is expected that medical devices will increasingly operate in environments where emissions from mobile RF/wireless transmitters are increasingly common.

For Healthcare facilities, they should manage wireless equipment within their facility in accordance with the following guidelines, and neither unduly limit the use of otherwise beneficial technology or ignore the potential for EMI issues. Similar recommendations electromagnetic compatibility with medical devices should also be directly incorporated into corporate policies, strategic plans, and / or governance models.

For Wireless Equipment Manufacturers, they should have full understanding of the potential EMI issues that can arise in worse case scenarios with medical devices as well as other wireless equipment, and deploy their equipment and systems appropriately in accordance with the following recommendations.

OVERVIEW OF ISO TC215 TECHNICAL REPORT #21730: "HEALTH INFORMATICS - USE OF MOBILE WIRELESS COMMUNICATION AND COMPUTING TECHNOLOGY IN HEALTHCARE FACILITIES - RECOMMENDATIONS FOR ELECTROMAGNETIC COMPATIBILITY WITH MEDICAL DEVICES

Responsibility within healthcare facilities

Within the healthcare facility, clinical/biomedical engineers or other appropriate technical personnel (e.g., spectrum management, IT, telecom, and building services) should be the focal point for EMC, EMI mitigation, and EMC/EMI education and training. Qualifications are not specified in this document, although consideration should be given to appropriate education, expertise, and experience of the responsible individuals

Inventory within healthcare facilities

The medical device inventory within a healthcare facility should be managed to the extent possible and practical to ensure compatibility with the ever-increasing RF environment.

a) In the purchase of new medical devices by healthcare facilities, every effort should be made to ensure the equipment meets (and exceeds if possible) minimum EMC immunity requirements set out by IEC 60601-1-2:2001 or other appropriate medical device EMC standard. Older equipment found to be particularly susceptible to EMI caused by mobile wireless transmitters should be phased out as is possible and practical within the healthcare facility budget.

b) While significant modifications to medical devices should not be made by healthcare facilities, certain simple precautions can be taken to reduce the risk of EMI caused by mobile wireless transmitters. EMI susceptibility in all medical devices can be reduced by positioning cables, sensors, and electrical accessories in such a way as to increase the distance between these components and RF transmitters operating in the area. Life-supporting medical devices or those known or suspected of being susceptible to EMI can be positioned away from high traffic areas or adjoining rooms where mobile wireless equipment may be in routine operation.

Testing within healthcare facilities

The **IEEE / ANSI C63.18** protocol is recommended for comprehensive ad hoc, on site testing of all mobile wireless equipment that might be used in the healthcare facility by doctors, staff, visitors, or patients. However, it is fully understood that exhaustive testing is rarely feasible, and different needs, resources, and personnel constraints of the healthcare facility may dictate widely different approaches. General recommendations regarding EMC testing are as follows:

a) Testing should be performed, whenever possible and practical, on selected medical devices in the equipment inventory that are considered to have life supporting functions (i.e., according to the prioritization recommendations of ANSI C63.18) using one of the mobile handsets as a test transmitter (see ANSI C63.18 for details on the test protocol).

b) Testing should take special consideration of older medical devices, life-supporting medical devices, and any device where EMI is suspected. Testing can be extended to other medical devices where feasible and practical (see ANSI C63.18 for details on a recommended prioritization).

c) Periodic testing should be performed on a regular schedule (e.g., once per year), and especially after changes such as the introduction of new communication devices, new medical equipment, or significant repositioning on a regular basis

d) If comprehensive testing of mobile wireless equipment is not possible, focused testing on mobile wireless equipment routinely operating within the healthcare facility that can transmit at higher power (e.g., two-way radios, mobile / cellular phones) may be most appropriate (see section 3, Table 1, and Annex A sections 4 and 5 for more detailed information about the frequency and RF output power for several types of wireless equipment). If testing of mobile wireless equipment is not possible at all, some information may be obtained by communicating with larger healthcare facilities that have performed prior testing or from ad hoc EMI testing databases found on the internet (one such ad hoc EMI testing database is currently being developed in cooperation with ASHE, although as of this revision it is not yet operational).

e) Assistance with obtaining transmitter equipment, setting the equipment in test mode for constant output at maximum power, and performing ad hoc testing can often be requested from mobile wireless equipment manufacturers and/or network providers.

f) Consideration may be given to have testing performed by an independent third party, in conjunction with the healthcare organization's clinical engineering group. The involvement of a third party may facilitate a consistent

and impartial evaluation of EMI issues and proposed management strategies, and more importantly may offer an independent analysis in cases where a further level of indemnity for the healthcare facility, equipment manufacturer, and/or network service provider is desired.

g) Medical devices found in ad hoc testing to be susceptible to EMI should be replaced whenever feasible and practical with more electromagnetically compatible devices, e.g. those compliant with new IEC 60601-1-2:2001 and other relevant immunity requirements. However, it should be noted that medical devices meeting 60601-1-2 can still be susceptible to emissions from mobile wireless equipment such as mobile / cellular phones at close range where the electromagnetic fields exceed the immunity testing levels specified in this standard.

h) Results from ad-hoc testing tend to be variable, due to variability in RF source power, medical-device differences, and test-site differences. It is important to understand that the primary function of ad-hoc testing is to identify unreasonably-susceptible medical devices so that they can be managed appropriately, not act as a quantitative assessment of their susceptibility.

Controlled use within healthcare facilities

For controlled mobile wireless equipment to be used by doctors and healthcare organization staff under managed conditions, it is recommended that necessary and sufficient procedures be implemented to identify, characterize, and mitigate potential EMI problems.

a) The **IEEE / ANSI C63.18** recommended practice (as outlined above) is the suggested test protocol for rapid ad hoc, on-site RF EMI testing for EMI identification and characterization.

1) Testing should be performed using the mobile wireless handsets to be used in the controlled system as a test transmitter. If multiple in-house systems are to be deployed, testing should be performed with each different RF signal. If new in-house systems are deployed, each different RF signal should be tested. Different EMI effects can be caused by different RF signals.

2) Ad hoc testing should be an ongoing effort, with a record of EMI test results kept including characterization of new medical device acquisitions and investigation / verification of reported EMI incidents, making any necessary adjustments to policy.

3) Periodic testing should be performed on a regular schedule (e.g., once per year), and especially after changes such as the introduction of new communication devices, new medical equipment, or significant repositioning on a regular basis.

4) Given the qualitative nature of the ANSI C63.18 ad hoc testing, even if no significant EMI issues are identified, nominal management policies including recommended minimum separation distances may still be prudent.

b) For mobile handsets that transmit at a constant output power, having no dynamic power control (e.g., standard two-way radios, family radios, two-way pagers, 802.11 systems), EMC management should involve ensuring adequate separation from identified susceptible medical devices. In the case of radio transmitters with relatively high constant power output (1 W or more), this may require significant separation distances and possibly necessitate their restriction from certain areas of the healthcare facility. In the case of pagers with extremely short burst transmissions or IEEE 802.11 a/b/g / Local Area Network or IEEE 802.15 / Bluetooth / Zigbee / IEEE 802.15.3a PAN equipment (see table 1 for more information about these) with relatively low constant power output (~10 milliwatts), the risk of EMI may be significantly less than for equipment such as two-way radios. Testing is still recommended whenever possible, although it is understood that it may reveal little susceptibility and the feasibility and practicality of all testing must be considered and prioritized.

c) If mobile wireless transmitters are dynamically power controlled (e.g., mobile / cellular phones, PDAs operating on wide area networks), EMC management should involve network characterization, design, and in-building engineering to supplement the wide area network as necessary to insure handsets are directed to transmit at RF power levels sufficient to minimize EMI issues. The existence of numerous shielding and reflecting objects in a healthcare facility may create areas with variations in downlink signal coverage, some of which could lead to significant intermittent changes in transmit power of the handsets causing them to deviate from their normal output power. Such areas should be characterized (by measuring existing signal strength with the mobile wireless handset set to a "trace" mode – this can often be done by the network service provider) and managed appropriately.

OVERVIEW OF ISO TC215 TECHNICAL REPORT #21730: "HEALTH INFORMATICS - USE OF MOBILE WIRELESS COMMUNICATION AND COMPUTING TECHNOLOGY IN HEALTHCARE FACILITIES - RECOMMENDATIONS FOR ELECTROMAGNETIC COMPATIBILITY WITH MEDICAL DEVICES

- d) Medical device management procedures may include identification through labelling, repositioning or other means to reduce exposure to the wireless emissions, or replacing particularly susceptible devices with newer model units. Because of medical device regulations, modifications to a medical device should only be made by the device manufacturer.
- e) User guidelines can be provided as an additional layer of management directing healthcare staff to maintain a predetermined and practical separation distance between their mobile wireless handsets and potentially susceptible medical devices (between 25 cm and 2 meters).
- f) The AAMI TIR 18 is recommended for additional details on medical device management and EMC/EMI guidelines.
- g) Testing of specific fixed-infrastructure components such as local electrical circuits and circuit breakers can be considered for testing if failure could represent a significant hazard, and if testing can be performed without placing the facility at risk.
- h) Healthcare facilities should actively manage spectrum usage (e.g, maintain a list of all controlled-use RF sources indicating where they are authorized to operate, as well as the maximal number of such units permitted within each area or zone).
- i) Wireless security issues (which are outside of the scope of this document) must be properly considered, otherwise patient safety may be threatened if the informatics system becomes compromised or incapacitated

Non-Controlled use within healthcare facilities

For non-controlled mobile wireless equipment that may be brought randomly into the healthcare facility by visitors, patients, or staff and transmit a variety of different signals at different output power levels:

- a) Separate EMC/EMI management policies than those listed for controlled mobile wireless handsets should be applied. While ad hoc testing and management solutions are always encouraged whenever possible, this may not be practical for every wireless system.

1) While certain mobile handsets may be able to operate compatibly throughout a healthcare facility environment, other mobile handsets may have greater potential to cause EMI events due to local differences in output power or signal type. As the number of handsets continues to increase and new models reduce size, internalize antennas, and combine technologies (i.e.; mobile phone / pager / PDA device / local area IEEE 802.11a/b/g / personal area IEEE 802.15.1 / UWB / IEEE 802.15.4, etc), it is becoming increasingly difficult to differentiate between RF transmitter types based upon visual appearance alone. Further confounders include the growing number of wireless headsets and accessories that relocate the actual RF transmitter to a pocket or purse, keeping them from obvious view even when in use. An increasing number of mobile wireless handsets can transmit multiple signal types, including data transmission that may use different bursting technologies (i.e., GPRS, WAP). Wireless laptop cards and PDAs may operate on either wide area (mobile phone-type) or local (IEEE 802.11.x - type) networks with different carrier frequencies, signal types, and power output. Ultimately, it may be impossible to enforce any policy that differentiates between different non-controlled mobile wireless handset types with regard to their use in the healthcare facility based upon visual appearance. For this reason, all non-controlled mobile wireless handsets should be treated with the same management / restrictions regardless of whether or not they appear to be the same as controlled handsets.

2) Restrictive policies might involve requesting that individuals not use their personal mobile wireless handsets in areas of the facility where potentially susceptible medical devices are used. This should involve requesting by appropriate signage or some other reliable mechanism that non-controlled mobile wireless equipment is turned off before entering areas where potentially susceptible life-supporting medical devices are commonly operating, as even well-intentioned individuals may feel compelled to receive and respond to incoming calls or messages.

3) Implementation and enforcement of restrictive policies should be facilitated by signs, especially in areas where potentially susceptible medical devices are commonly located, to make patients and visitors aware of the existing healthcare facility policy. Compliance with existing policy can be facilitated by defining numerous areas with easy access where the use of wireless handsets by patients, visitors, and staff is unlikely to interfere with medical devices.

4) Any restrictive policy should be balanced between an informed assessment of EMI risk and the increasing need among patients, visitors, and healthcare facility staff for mobile wireless communication and computing. In the extreme, healthcare facilities could ban the use of all non-controlled mobile wireless handsets altogether, although such measures are likely to be excessive from an EMI management perspective (58) and not responsive to the growing needs of individuals for direct access to mobile wireless communication, especially in times of emergency and crisis.

b) While instructing patients and visitors to maintain a minimum separation distance between their personal mobile wireless handsets and medical devices might theoretically act as a safeguard against EMI events, such a recommendation may be impractical in many facility areas, and further be exceedingly difficult to monitor and enforce. Such minimum separation requirements are not recommended as a primary management strategy. However, the minimum separation distances determined from ad hoc testing can be used as an added layer of management in areas where potentially susceptible life-supporting medical devices are commonly operating.

RF emissions from network sources

a) RF emissions from in-building system network antennas (WAN microcells or repeaters, LAN access points) are most appropriately managed by locating them in a place where separation distance mitigates medical device EMI effects, such as the roof of corridors and rooms.

b) RF emissions from base station sites physically located on healthcare facility roof-top or building structures should conform to existing national radio regulations to limit emissions directly into the supporting building structure.

Medical devices within healthcare facilities

a) Although outside the current scope of this recommendation, the placement and operation of RF-emitting medical devices within the healthcare environment is an area that should be carefully considered. There are many types of medical devices that generate and use electromagnetic energy for their medical function. For example, Electric scalpels (e.g. high frequency electrosurgical equipment) often generate RF and microwave fields for cauterization purposes, physio-diathermy units may emit 915, 433, 2450 MHz or other frequencies for deep tissue heating (36), and ultrasound machines may radiate up to their operating frequency of ~ 3 - 20 MHz. The healthcare facility should exercise caution in where and how these types of emitters are used in the vicinity of other potentially susceptible medical devices.

b) Electromagnetic type security and inventory systems such as metal detectors, anti-systems, and RFID emit signals that may disrupt potentially susceptible medical devices. The policies and practices of the healthcare facility should address this equipment. For example, RFID tags used in the healthcare environment may be passive emitters, activated by inductive processes when brought into proximity of RFID readers. However, the readers may emit high field strength magnetic fields and should be included as a transmitter in ad hoc testing and in EMC/EMI management policies. The recently published ASTM F 2401-04 "Standard Procedures for Security Checkpoint Metal Detector Screening of Persons with Medical Devices" provides useful information [57]

c) For medical devices used outside the healthcare facility in a domiciliary setting, such as dialysis equipment, blood glucose analyser, infusion pumps, etc, instruction should be provided to patients advising them to maintain at least 1 meter of separation distance between the medical device and mobile wireless equipment while it is in operation.

Abstract

In the current work, we study the EMC problem that involves the usage of an electroencefalographer in an environment with electromagnetic radiation produced by a WiFi access point.

The experimental setup was situated in an anechoic chamber so that no electromagnetic interference would affect the measurements. The amplifier room, outside the anechoic room, situated the other part of the experimental apparatus. 32 electrodes entered a low-pass filter placed at the boundary wall of the Faraday screen room. The signal was amplified, before entering a 32-bit analog to digital converter. The recording frequency was at 1 kHz.

The wireless access point operated at the typical frequency band of 2.4 – 2.4835 GHz and the maximum EIRP allowed in Europe that is 100mW. The distance of the access point to the electroencefalographer was 10cm. Two sets of measurements were performed. One with measuring the noise of the system and the other with the WiFi transmitter switched on.

The results showed that there was no interference of the WiFi Access point to the measured signals. This is of great importance because of the great expansion of wireless technology.

Introduction

Since the early 1990s, reports of medical device failure from electromagnetic interference have increased [1, 2]. This is due to several factors. The number of electronically controlled medical devices has burgeoned in hospitals and other medical facilities. The modern instruments are often more sensitive to electromagnetic interference (EMI) because they incorporate low power integrated electronic circuitry that can be much more sensitive to electromagnetic fields than their electrical and electromechanical predecessors. Digital wireless communications systems often utilize pulsed amplitude modulation, a type of modulation that can enhance the potential for EMI.

The European Union has gotten much of attention with regard to the regulation of electromagnetic compatibility (EMC) and medical electronics. Today, most medical EMC regulations originate within the International Electro technical Commission (IEC). The standard EN60601-1-2 [5] defines limits for emissions and levels of immunity and was updated to encompass the frequencies used by mobile phones and other communication technologies such as wireless local area networks (WLAN). The IEC standard states that electronic medical equipment must operate normally in electric field intensity of 3 V/m and at a 10 V/m threshold for life – sustaining equipment.

The Electroencephalograph (EEG) is a recording equipment of brain signals with typical voltage of 100 μ V and frequency range (EEG bands) 0.5 Hz up to several hundreds Hz. The EEG is connected directly to the patient in order to detect these small physiological signals which are then amplified. The EEG is known to be very sensitive to EMI due to the fact that the pulsed RF signals maybe demodulated by non-linear elements in amplifier circuits. [Robinson 2003]. Morrisey et al. reported distortion of EEG bands throughout the 0-70 Hz range during full power exposure to CDMA and GSM signals for both frequencies of 1.800 and 1900 MHz at distances of between 0.25 to 0.5 m.[Morrisey 2002].

Wireless Local Area Networks (WLANs) in a hospital typically consist of multiple antenna sites (known as base stations) interspersed throughout the hospital building that connect to a central “hub” or “router” unit. This latter unit connects the WLAN with the wired hospital network. WLANs transmit and receive signals with various handheld devices (or laptop computers, etc) as these devices roam throughout the coverage net work in the building. WLANs typically use the 802.11 standards that operate on frequencies around 2.45 GHz and 5.8 GHz. The handheld devices are not power controlled, but transmit at a very low constant power (on the order of 1-10 milliwatts) as they are designed to never be very far away from the nearest network node. As a consequence, the likelihood of electromagnetic interference of WLANs with critical and life support medical equipment is very small, since they transmit at power levels that are well below the IEC recommended levels. The WLAN base stations transmit at a higher power level (typically around 500 mW), which increases the chances for electromagnetic interference. Research by [13] revealed that peak values of such base stations often exceed the critical 10V/m field strength value.

Taking into account the above considerations, in our current work, we study the EMC status that involves the usage of an electroencephalograph in an environment infested with electromagnetic radiation produced by a WiFi Access Point. The purpose is to observe the effects of the WiFi signal on the EEG signal.

Materials and Methods

The experimental setup (Fig 1) was situated in a Faraday chamber so that no electromagnetic interference would affect the measurements. A head phantom was placed in the chamber and the signals were recorded from thirty two electrodes (Fp1, Fp2, Fpz, AFz, F2, F3, F4, F7, F8, FC1, FC2, FC5, FC6, C2, C3, C4, A1, A2, CP1, CP2, CP5, CP6, P3, P4, Pz, T3, T4, T5, T6, O1, O2, Oz) with a surface of Ag/ AgCl, which were placed on the scalp of the model-head. The electrodes were positioned according to the International 10-20 system of electroencephalography [8]. The measured magnitude was the voltage at the edges of a 2 k Ω resistance placed between each electrode and a common ground. The total electrode impedances were below 5 k Ω . The amplifier room, outside the Faraday room, situated the other part of the experimental apparatus. The electrodes entered a low-pass filter placed at the boundary wall of the Faraday screen room. The filter cut frequencies over 35 Hz so that the signal of the power supply network which is at 50 Hz would not interfere with the signal. The signal was amplified by a Braintronics DIFF/ISO-1032 amplifier, before entering a 32- bit analogue to digital converter (NI SCB-68) which has a GPIB output. The digitized signal comprises an input for a Data Acquisition Card (32 bit NI 6035E DAQ Card). The PC with the DAQ Card ran a LabView program for the recording of the signals, which can be monitored by an on-screen graphical representation. The recording frequency was at 1

kHz. Another PC, connected with the one described above, ran a program which triggered the other PC to save the brain signals whenever the user wanted. The recording time was 1.5 sec so the saved signal consisted of 1500 values. The total task consisted of 55 repetitions.

The WiFi Access Point was placed in the Faraday room and made a link with a laptop that was inside the room. The WiFi signal was radiated by a dual dipole antenna, with 20dBm power and QPSK modulation. The Access Point was placed at a distance of 1m from the head.

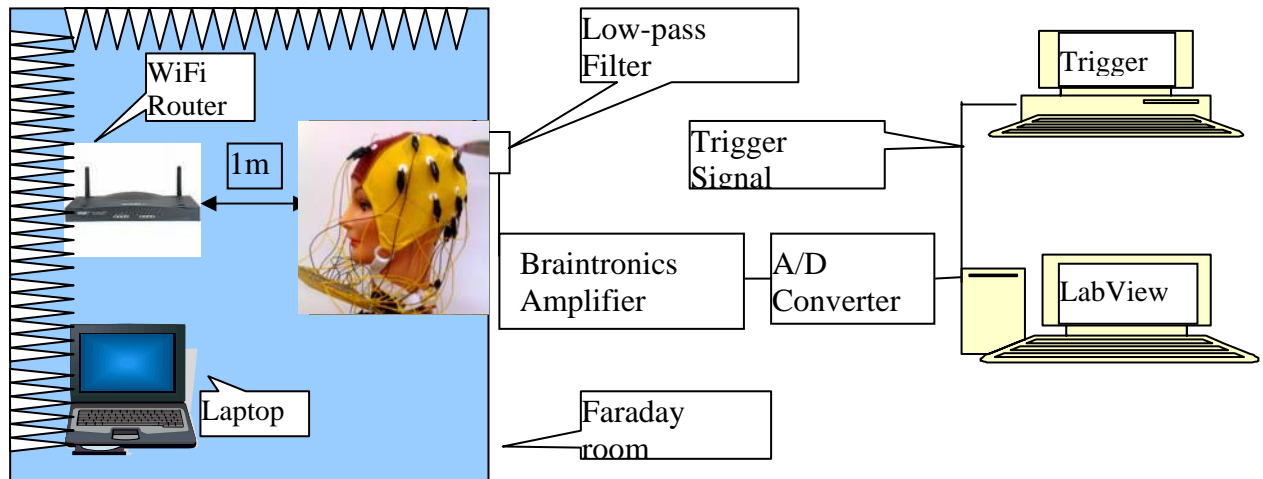

Figure1. Experimental Setup

The experimental procedure was done twice. The first time the WiFi Access Point was off and practically the noise of the device was measured and the second time the WiFi was functioning.

Regarding the collected data analysis, in order to optimize the signal to noise ratio (SNR) the grand average across the 55 repetitions for each channel was calculated according to the following equation:

$$\bar{V}_t = \frac{1}{55} * \sum_{j=1}^{55} V_{jt}$$

Where V_{jt} is the value that results after the subtraction of the amplification and the average referencing and corresponds at the time t of the trial j . This SNR optimization procedure is considered a standard practice when it comes to brain signal measurements, which are generally considered to be quite noisy. (Roth et al., 1995, pp.805-910)

The final data for analysis for each EMF condition consisted of 1500 amplitude values for each electrode, expressed in μ Volts corresponding to the 1500 msec of the time period as described above.

For each electrode, the following magnitudes were also calculated:

- the energy E of the recorded signals ($E=V_t^2$)
- the amplitude in the frequency domain by using the Fourier Transform (FFT).

Data analysis

The differences between the values of the energy at the two EMF conditions were calculated for each of the thirty two leads. The data were also compared to real EEG recordings at certain representative electrodes. The mean values and the standard deviations of the final data were calculated for each group (WiFi Off, WiFi On, EEG) at these electrodes.

Results

The data analysis revealed that the maximum difference between the values of the signal energies for each EMF was 0.7 Joules with the exception of T5 electrode, which is a small value if compared with the energy values. Figure 1 is quite helpful in explaining this fact. The white bars denote the calculated energy in the absence of the WiFi signal while the black bars denote the signal energy in the presence of the WiFi signal.

Figure 2. Averaged Energy at each electrode and each radiation condition. . The white bars denote the calculated energy in the absence of the WiFi signal while the black bars denote the signal energy in the presence of the WiFi signal.

Table 1 shows the mean values and the standard deviations at some representative electrodes, of the three groups of data at different conditions: absence of WiFi Signal, presence of the WiFi signal and EEG recordings. It is notable that the mean values and the standard deviations for the first two cases (WiFi Off, WiFi On) are very similar. The comparison of these values to the respective values of the data that come from human measurements reveals great variation.

Electrode	Mean Values			SD		
	WiFi Off (Noise)	WiFi On	Human	WiFi Off (Noise)	WiFi	Human

Figure 3. Grand averaged amplitudes for the three experimental conditions at the electrode O1

Discussion

From the data analysis and the results which aroused, there is no evidence that a WiFi signal at a distance of 1m from EEG electrodes causes interference at the EEG recordings. WiFi is a low power protocol that has flexible power settings and can be deployed in various conditions in order to ensure that all radiation is well within the limits set even by the most strict hospital authority. Other tests [14] indicate that not only WiFi shows no interference to medical equipment but has the edge when compared to other wireless technologies. Wireless communication is a promising opportunity for future medical systems in the hospital. Today's wireless standards with moderate output power represents no real danger for the operation of medical equipment [14] and seems to be suitable for medical environment even with several wireless devices used simultaneously. The various applications that hospitals can create through the use of WiFi in a quick and cost effective fashion have been the subject of many a discussions, wireless patient monitoring in steady state [15] or in IC units or in OR units [14,16] is an application of great importance that will greatly improve the working conditions of the staff but moreover it will make the care of patients more efficient. Even though the results indicate that there is more tests are no interference between EEG and WiFi we need to investigate further in order to verify the suitability and assure the reliability of WiFi communication in medical equipment of any sort.

ABSTRACT

The present study was performed to evaluate effects of a 2-year exposure to an electromagnetic near-field (EMF) equivalent to that generated by cellular phones on tumor development in the central nervous system (CNS) of rats which were born from ENU-treated F344 mother rats. A total of 500 pups were divided into 5 groups, each composed of 50 males and 50 females. A 1.95 GHz W-CDMA signal for IMT-2000, was used for the exposure of the rat head starting from 5 weeks of age, 90 min a day, 5 days a week, for 104 weeks. Brain average specific absorption rate (SAR) was designed to be 0.67 and 2.0 W/kg for low and high exposures, respectively. Whole-body average SAR was less than 0.4 W/kg. The incidence and number of brain tumors in female rats exposed to 1.95 GHz EMF had a tendency to be increased but there was no statistical significance. Overall, no increase in their incidences or numbers per group, either in the males or females, was detected in the EMF-exposed groups. Thus, under the present experimental conditions, 1.95 GHz W-CDMA signal for IMT-2000 exposure to the heads of rats for a 2-year period did not accelerate or affect ENU-initiated brain tumorigenesis.

INTRODUCTION

Since there is serious concern that exposure to an electromagnetic field (EMF) due to cellular phones is associated with an increase risk of disease such as brain dysfunction and/or brain tumor development, many epidemiological and experimental research studies to explore this possibility. However, none of epidemiological studies revealed a clear association between exposure to EMF and development of brain tumors. Furthermore, none of 5 long-term (2-year period) animal experiments which had been performed demonstrated the presence of association of exposure to time-division multiple access (TDMA) or frequency-modulated signals with tumor development in the central nervous system of rats. Recently we also conducted a 2-year EMF exposure experiment in an ENU-exposed rat model with a 1.439-GHz TDMA signal for the Personal Digital Cellular (PDC), Japanese standard cellular system at brain average specific absorption rates (SARs) of 0.67 and 2.0 W/kg for low and high exposures. The results disclosed no inter-group differences in body weights, food

consumption, or survival rates and no increase in the brain and spinal tumor incidences or numbers per group, either in males or females of the EMF-exposed groups [Shirai, et al. 2005].

Recently the International Telecommunication Union (ITU) has introduced the new mobile telecommunication system, i.e., International Mobile Telecommunication 2000 (IMT-2000) which has also been named the 3rd generation (3G). The wide-band code division multiple access (W-CDMA) is also termed the Universal Mobile Telecommunication System (UMTS) in the EU. The first IMT-2000 service was started in Japan in 2001. This service, the freedom of mobile multimedia access (FOMA) by NTT DoCoMo, uses W-CDMA signals and the 1.95 GHz region for up-links and the 2.14 GHz region for down links. The number of subscribers to the W-CDMA system in Japan was about 28 million in April 2006 while that to the TDMA systems was about 41 million. Because the number of W-CDMA users is rapidly increasing, this type of signal will probably become the most major digital signal for the Japanese general public in near future.

Therefore, the present study was designed as a first long-term investigation of effects of chronic exposure to 1.95-GHz W-CDMA signals for IMT-2000 cellular system on development of ENU-induced CNS tumors in F344 rats. It was conducted in compliance with the Good Laboratory Practice (GLP) Standards of the Japanese Ministry of Health and Welfare Ordinance No. 21. This is the first experimental result on a long-term effects of IMT-2000 cellular system on development of central nervous system tumors.

MATERIALS AND METHODS

A total of 100 pregnant F344 rats were purchased from Charles River Japan (Atsugi, Kanagawa Japan) and given a single intravenous administration of ENU on gestational day 18. ENU (Nacalai Tesque Tokyo, Japan) was dissolved in physiological saline for this purpose and injected into the tail vein at a dose of 4 mg/ml/kg body weight. ENU-exposed pups of both sexes were allocated to 4 groups, each composed of 50 females and 50 males. Pups (50 males and 50 females) from mothers that received the vehicle instead of ENU served as complete controls. Dummy animals were used to cover any vacancy in EMF exposure boxes due to interim death to maintain the exposure conditions unchanged. All animals were allowed free access to pelleted diet and drinking water.

The rats in Groups 1 to 5 were exposed to EMF; Group 1 was a complete control without any treatment. Group 2 received ENU alone and was kept in cages throughout the experiment. Group 3 was given ENU set in exposure boxes in the same manner as in Groups 4 and 5 but with no actual exposure to EMF (sham exposure group). Groups 4 and 5, given ENU, then were exposed to EMF at low (SAR: 0.67 W/kg) and high (SAR: 2.0 W/kg) levels, respectively.

The exposure box was 90 x 90 x 60 cm. Ten rats fixed individually in plastic tubes were set on disk-shaped plates like a carousel with the nose pointing to the center. Each plate was 65 cm in diameter, with adjustable height supported by a center hollow cylinder pole. A resonant monopole antenna for 1.95 GHz was set from the ceiling of the exposure box in order to fit in the center of the disk-shaped plate. The distance between the antenna and each rat nose was set at 30 mm.

A 1.95-GHz W-CDMA signal from Cellular Phones for IMT-2000 Cellular system was applied. Long-term intermittent exposure to the heads of the rats (90 min a day, 5 days a week, Monday through Friday) was started at 5 weeks of age and continued for 104 weeks. All exposures including sham exposure were controlled with the assistance of a computer system. If the number of rats became less than 10 in an exposure box due to loss through mortality, dummy rats were used to maintain the symmetrical arrangement of animals and the scheduled specific absorption rate (SAR) of EMF exposure.

SAR distributions in rats were evaluated by numerical dosimetry with the Finite Difference Time Domain method (FDTD). Brain average SAR was set at levels, 0.67 and 2.0 W/kg, respectively. Whole-body average SAR averaged over the 2-year experimental period was limited within lower level which cannot cause any thermal effects; the highest whole-body averaged SAR was 0.464 W/kg which is much lower than 4 W/kg, the threshold for thermal effects.

All surviving animals after the 104 week-exposure to EMF were killed under light anesthesia with ethyl ether and aorta blood was collected from all rats for hematology analysis, before a complete autopsy was performed. Organ weights were measured for the brain, heart, liver, kidney, spleen, pituitary gland, adrenal glands, testes and ovaries. All organs including the CNS and macroscopically observable lesions were fixed in 10% buffered formalin routinely processed for embedding in paraffin and sections (4 mm thickness) were stained with H & E for histological examination. Rats that died or became moribund during the experiment were also autopsied.

RESULTS

There were no significant differences in growth rates between rats receiving maternal ENU and untreated controls (Group 1) in either males or females. Restraint of rats in the plastic holders in the exposure

LACK OF PROMOTING EFFECTS OF CHRONIC EXPOSURE TO 1.95-GHZ W-CDMA SIGNALS FOR IMT-2000 CELLULAR SYSTEM ON DEVELOPMENT OF N-ETHYLNITROSOUREA-INDUCED CENTRAL NERVOUS SYSTEM TUMORS IN F344 RATS

boxes itself suppressed growth, particularly in the males, but this suppression was not exacerbated by actual EMF exposure. No significant inter-group differences in survival rates were observed in either sex. No clear increase in death rates with EMF exposure was observed in males or females. There were no significant differences in food consumption among groups throughout the experiment in either the females or the males. There were no inter-group differences in the relative organ weights of the brain, heart, liver, kidney, spleen, pituitary gland, adrenal glands and testes or ovaries.

In this study, one CNS tumor was also observed in a female not receiving ENU. The lesions were astrocytomas, oligodendrogliomas, mixed gliomas, ependymomas, meningiomas, granular cell tumors and malignant reticulosis. The major type was the astrocytoma. The incidences of brain tumors in the females ranged from 2 to 22% and the numbers of rats ranged from 1 to 11. The incidences and numbers of brain tumors were very similar in males and females. While values in female rats exposed to 1.95-GHz W-CDMA signals for IMT-2000 had a tendency to be increased, this was not statistically significant. Spinal cord tumors were sporadically found in the males but not the females. There were no statistically significant differences in CNS tumors in males among the groups given ENU. Thus, the data for both sexes indicate that EMF does not accelerate ENU-initiated CNS tumor development.

Besides CNS tumors, sporadic tumors were noted in other organs/tissues. Among these tumors, skin fibromas and large granular lymphocytic leukemia were less frequent in the EMF exposed males and there was a statistical significance between sham exposed and the high dose EMF group at $p < 0.05$.

DISCUSSION

In the literature, there are conflicting epidemiological data regarding the risk of EMF exposure for brain tumor development; some demonstrating very small association between workers in electrical industry and in the US Air Force population and brain tumors. However, there are five recent epidemiological studies that did not demonstrate any association between cellular telephone use and brain tumor risk.

With such conflicting epidemiological data, long-term animal experiments are essential for scientific evaluation of the risk of EMF with reference to brain tumor development. Four animal studies specifically targeting this question had already been performed prior to the present work. Neither 2-year animal bioassays with digital nor frequency-modulated signals found any detrimental effects of EMF exposure after intrauterine administration of ENU. A similar experiment with Sprague-Dawley rats carried out by others resulted in no initiation or promotion of brain tumors by any of the RF fields tested. Our group also previously conducted a long-term exposure animal experiment with intrauterine treatment with ENU for brain tumor initiation and we concluded that exposure to 1.439-GHz TDMA signal for 1.5 h/day, 5 days for 2-year period, did not accelerate ENU-initiated CNS tumor development in rats.

The present experimental design with 1.95GHz W-CDMA signals for IMT-2000 cellular system was also planned by the Committee of the Study on Human Exposure to EMF in Japan established in 1997 with the aim of scientifically clarifying any effects of radio waves from mobile telephone terminals on the human body. The whole body average SAR was limited as far as possible in order to avoid significant thermal stress and was less than 0.464 W/Kg. In the present experiment, there were no statistically significant inter-group differences in the incidences of CNS tumors in either males or females initiated with ENU although there was a tendency of slight increase in brain tumor development in the females exposed to EMF. No increase in spinal tumor development by EMF exposure was observed in either sex. Furthermore, development of tumors in organs other than CNS was not enhanced. Thus, it can be stated that the present data demonstrate that 1.95-GHz W-CDMA signals for IMT-2000 Japanese cellular system at a brain average SAR of 0.67 or 2.0W/kg for 2 years do not possess promotion potential for ENU-initiated CNS tumor development in either sex of F344 rats. In our previous study with 1.439 GHz TDMA signal, the incidences of pituitary tumor in both sexes received ENU showed a tendency for increase, but were clearly suppressed by 2.0 W/kg EMF, with statistical significance in males. However, such increase by ENU and suppression by EMF were not evident in the present study. Since the increase of pituitary tumor development in ENU-treated animals was concluded to be within the wide range of background data, the present data for pituitary tumor incidence seem reasonable.

In conclusion, the present large scale 2-year exposure experiment to 1.95GHz W-CDMA signals for IMT-2000 cellular system demonstrated that EMF at brain average SAR of 0.67 or 2.0W/kg does not promote ENU-induced rat brain carcinogenesis, providing additional evidence in support of no association between EMF and brain tumor risk in man.

Abstract

Changes in membrane order are known to alter the function of integral proteins. Consequently, microwave induced changes of membrane lipid order may have physiological implications. The detailed biophysical mechanisms for these effects are not currently available and experiments on in vitro models are expected to offer the keys to understanding the nature of microwaves non-thermal and windowed effects.

We studied the changes in membrane fluidity (fluorescence depolarization) and generalized polarization of human platelets extracted from freshly donated blood, induced by irradiation with 2.45 GHz microwaves, CW at 24 mW incident power, SAR 10 W/kg. The experimental arrangement consisted mainly in a 2.45 GHz generator of adjustable output power in the range of 0 – 30 mW and a modified conventional coaxial probe used for two functions: as impedance matching device and as microwave (MW) irradiating antenna. Irradiation of samples during fluorescence anisotropy and generalized polarization records was made by introducing the antenna into the fluorometric cuvette. Changes of the same membrane parameters of a liposome suspension irradiated by microwaves was performed in order to have as reference a simple lipid bilayer, consisting of a single type of lipids.

Studies of membrane phase-transition temperature and other physical and chemical parameters lead to the conclusion that the liposome and platelet membranes, whose isothermal electric susceptibility is dramatically increased around phase-transition temperature, undergo order changes by interacting with oscillating electromagnetic field; these are reflected in the observed shift of the phase transition temperature of the microwave exposed liposomes comparatively to the sham exposed samples as well as in the higher values of generalized polarization (GP) of the cell/liposome membrane.

Membrane dipolar components such as polar amino acid side chains and cell membrane associated bound water which undergo orientation resulting in rotational motions with an associated time constant similar to the wave number of the impressed oscillating electromagnetic field, are the most probable targets which trigger the observed membrane order changes.

Introduction

Decades of experimental and theoretical research stay behind the attempts to reveal and account for the observed biological effects of RF and microwaves. Despite the investment of creativity, funds and hard work, few sound statements and facts concerning the specific interaction of microwaves with living structures/cells are available.

In our work, we choose simple phenomena and biological models in the attempt to dissociate the specific microwave interaction with the substrate from the non-specific thermal effect; the assumption is that while a great part of incident microwaves energy is dissipated as heat, the other part is absorbed resonantly by specific structures accounting for non-thermal “biological effects”.

Two phenomena were chosen to analyse the specific interaction mechanisms.

1/The changes of *lipid packing in membrane bilayer* potentially induced by microwaves and formally reflected in a fluorescent marker mobility and in critical events accompanying the phase transition of the lipid bilayer. These changes would shift the temperature dependence curves and phase transition temperature in irradiated versus control samples as shown by fluorescence depolarization recordings.

2/ The change in *generalized membrane polarizability* induced by microwave application which must be reflected in fluorescent emission of Laurdan – a fluorescent dye, sensitive to polarization of hydrophilic environment within the lipid bilayer.

Method and results

Fluorescence depolarization

Fluorescence depolarization measurements of a membrane fluorescent marker (TMA-DPH in our case) provide information about the rigidity of lipid tails packing around the site of marker insertion. As higher is fluorescence anisotropy (r) as less fluid may be considered the membrane in the region of marker insertion (in case of TMA-DPH, below the polar heads in the outer lipid layer). A lipid bilayer is characterized by a specific phase – transition temperature, when it switches from a gel-like organization (lipid packing) to a liquid-crystalline organization, when lipid packing is looser (more fluid). The degree of looseness of lipid packing is critical for many membrane functions which rely on protein conformational changes within or across the membrane. It is considered that subtle conformational changes of proteins which occur along the signal transduction pathways may be hindered under low level microwave irradiation although no plausible physical mechanism for explaining this effect is yet available.

Here we use a simple model of lipid bilayer, *the liposome membrane*, to check if lipid packing is influenced by microwave irradiation. The fluorescence marker used is a TMA-DPH molecule.

Fig.4 Fluorescence anisotropy of human platelet membranes vs. temperature increase at thermostat (black) and microwave (red) heating

Generalized polarization (GP)

Laurdan (6-dodecanoyl-2-(dimethylamino)-naphthalene) is a fluorescent dye which spontaneously incorporates into phospholipid membranes due to its long hydrophobic tail, as shown in the scheme below:

The molecule in the ground state has a very low dipole moment, while excited it has a high dipole (due to the existence of donor and acceptor functional groups).

When the membrane contains dipolar molecules (e.g. water), these molecules will strongly interact with the excited form of Laurdan, shifting its emission spectrum toward lower energies (higher wavelengths), because part of the excitation energy is dissipated in the reorientation process. This phenomenon is illustrated in the diagram below:

In MW fields, the permanent dipoles of water are supposed to align along the electric field lines. This “ordering” phenomenon of the molecules inside the membrane will hinder the energy transfer process between the excited molecules of Laurdan and the surrounding water molecules, compared with the same process in a non-irradiated sample. Thus, when heating a sample, the profiles of the plots representing the emission maxima position vs. temperature, will depend on the heating procedure (“thermal” or by MW irradiation).

ORDER CHANGES IN CELL MEMBRANE INDUCED BY APPLIED 2.45 GHz EMF

In the case of simple membranes, containing one single component, like liposomes, the plot of λ_{\max} vs. temperature has an S-shaped aspect, showing a quite sharp inflexion point corresponding to the phase transition temperature of the phospholipid used for liposomes preparation.

Fig.5 Modification of emission spectra of Laurdan in 1,2-dimyristoyl-sn-glycero-3-phosphocholine (DMPC) liposomes, induced by “thermal” heating. a) Aspect of emission spectra at two extreme temperatures (14 and 40 °C); b) Shift of the emission maxima as a function of temperature.

As concerns the generalized polarization, it depends on the temperature in the same S-shaped way as the emission maxima, but in a less well defined manner, presenting the inflexion point at approximately the same temperature:

Fig.6 The temperature dependence of generalized polarization. The difference between the values of the inflexion point as determined by GP and λ_{\max} lays within the standard error of the two computation methods

When the same heating is performed by applying MW, the corresponding plot looks like:

Fig.7 General polarization of DMPC liposome suspension cooled in the presence (red curve) and the absence (black curve) microwave irradiation (SAR 10mW/g).

Containing cholesterol and many other lipidic or non-lipidic components, many cell membranes do not elicit a clear critical temperature of phase transition, the different phases coexisting in various proportions. In the figure below, the record of GP at warming and cooling of platelets suspension in the absence of MW irradiation is shown.

Fig.8 General polarization of human platelets suspension in HBBS buffer as evaluated by Laurdan fluorescence. No obvious inflection point (phase transition temperature) can be noticed.

ORDER CHANGES IN CELL MEMBRANE INDUCED BY APPLIED 2.45 GHz EMF

Fig.9 Generalized polarization of human platelets suspension in HBBS buffer as evaluated by Laurdan fluorescence. Higher GP of irradiated sample (red) show a predominance of non-relaxed Laurdan population

nm

Discussion

The higher values of generalized polarization in irradiated lipid vesicles as well as in platelets reflect formally an increase in population of non-relaxed Laurdan molecules which cannot orient locally the polar, hydrophilic molecules (water). We could expect this, since water molecules are already oriented by microwave field, contributing to a more rigid, gel-like lattice at low temperatures (see figure 7). This is also why the phase – transition temperature is higher in irradiated liposome sample. As system pass to a liquid-crystal phase (above T_c), the difference between the two samples vanishes since thermal motion oppose the dipole orienting effect of the field.

The same effect can be observed in recording the fluorescence anisotropy based on emission of relaxed and nonrelaxed laurdan molecules. Under microwave irradiation the anisotropy of relaxed Laurdan emission is lower comparatively to that of the non-relaxed Laurdan due to the greater mobility of the fluorescent marker in the lipid environment when it cannot strongly orient the neighboring dipoles (water, aminoacids) already oriented in the direction of the applied field.

In case of TMA-DPH fluorescence measurements the local mobility of lipid tails packed within the membrane bilayer is followed up. While in case of model liposome membrane no dramatic effect of irradiation was observed (fig.3), in case of platelet membrane a pronounced loosening (decrease of fluorescence anisotropy) of lipid packing is noticed (fig.4) similar to that recorded when using Laurdan (fig.10).

Conclusion

Based on evidence of the effects of radiofrequency fields in different biological endpoints, it has been suggested (Adey 1993), that co-operative interactions on the surface of cell membranes may allow weak fields to influence cellular processes through signal amplification and transduction processes.

At frequency used in our measurements (2.45 GHz), the basic interaction mechanism is the rotation of molecules in which positive and negative charges are separated in space (polar molecules). The most common such molecule in biological matter is water. Polar molecules tend to align themselves with the electric field and, as this oscillates, they tend to follow these oscillations. In this process energy is dissipated in the form of heat.

To discuss on *long lasting* effects of microwave application on a living system is only meaningful in terms of interference with signal pathways and this is, most probable, the specific “nonthermal” effect of microwaves although, as mentioned above, it may be accompanied by system heating.

An example of (interfacial) membrane polarity modulating the binding of signal molecules is the case of protein kinase C (PKC). This enzyme plays an important role in signal transduction. It is an amphitropic enzyme, existing in both aqueous and membrane phases. Binding of PKC to membranes increases its activity against most substrates. Membrane interfacial properties affect both the binding of the enzyme to a membrane as well as the activity of the enzyme in the membrane-bound state (Giorgione et al., 1998).

ORDER CHANGES IN CELL MEMBRANE INDUCED BY APPLIED 2.45 GHz EMF

Our experiments provide the evidence that in simple bilayer systems (liposomes) as well as in a living cell membrane there is a change in local order of lipid packing (membrane fluidity) and polar molecules orientation induced by microwave irradiation. These changes are consistent with many reported cellular effects of microwaves and provide a meaningful biophysical mechanism for them.

Abstract

Numerous studies have reported biological effects from exposure to electromagnetic fields both in the ELF and RF ranges, but there is a lack of consensus about the validity of observed effects. In part this is due to replication difficulties. At the core of this issue is the fact that observed effects, while significant, can be of a subtle nature and can be easily masked by equally subtle changes in experimental conditions. The result is that effects that are observed in one experimental setting may not be observed in another seemingly equivalent setting. An alternate approach to verify the validity of observed effects that overcomes the difficulties associated with attempting to duplicate experimental conditions is to intentionally use an inhibition factor to demonstrate that observed effects can be elicited or negated at will. Our own research and that of others supports the notion that a universal inhibition factor is ELF electromagnetic noise. The superposition of ELF noise to inhibit biological effects elicited by exposure to electromagnetic fields has been found to be effective in all instances tested. Inhibited effects include: changes in enzymatic activity, changes in hormone levels, changes in oncogene transcript levels, alterations in gap junction intercellular communication, increases in DNA breaks, activation of stress proteins, increases in cell proliferation, teratogenic effects, and memory effects. The superposition of ELF noise has been shown to be equally effective in blocking ELF and RF induced effects. A physical understanding of how EM noise acts to block EMF induced effects can be formulated in terms of a detection process of the EM stimulus

analogous to the detection of chemical gradients in bacterial chemotaxis. This theory hypothesizes a temporal sensing mechanism involving two characteristic time constants: τ_a , the “averaging” time (~ 0.05 s), and τ_m , the “memory” time (~ 5 s). To elicit a full response a stimulus of constant intensity over τ_a must be applied for a time period greater than τ_m . The superposition of EM noise effectively inhibits the response by destroying amplitude uniformity of the EM stimulus over the required time scale.

Key words: ELF noise, temporal sensing, inhibition factor

Introduction

As far back as the 1980's reports about so-called nonthermal biological effects of exposure to weak electromagnetic fields (EMFs) were being widely circulated (Luben et al. 1982). These reports created a great deal of controversy as they went against the then commonly held belief that electromagnetic exposure could be of biological consequence only when the energy transfer was sufficient to produce measurable increases in temperature. Today, more than 25 years later and after hundreds of studies the controversy still remains. But the source of the controversy is not that biological effects from exposure to nonthermal fields have not been observed, but rather that biological mechanisms that explain the observed phenomena are still not well understood and cannot be easily explained, leading some to believe that effects are not plausible in spite of the evidence (Adair 1991, 2003).

All life on earth has evolved in the presence of environmental factors that include a broad spectrum of electromagnetic radiation. Much of this radiation is from natural sources that have been an essentially constant part of the environment in recorded time. But the technological leap that has taken place over the last 75 years or so has substantially increased the background radiation. This increase is particularly evident in the Extremely Low Frequency (ELF) range due to the ever-expanding electric power distribution grid, and in the Radio Frequency (RF) range due to the exponential growth of telecommunication networks. The increased exposure to man-made fields has fuelled the interest in understanding biological interactions, not only as a means to gain scientific knowledge, but also to assist in the setting of regulatory guidelines for exposure to such fields.

The issue of regulatory guidelines is most relevant in connection with the use of the ubiquitous cellular phone. Present guidelines, which coincide with practical limitations for the deployment of these devices, are based on the assumption that only effects accompanied by strong thermal interactions are likely. Yet there are hundreds of studies that show effects from nonthermal exposure (Adair 2003). Most of the observed effects are of a subtle nature and are therefore susceptible to numerous factors that make replication difficult. In part due to replication difficulties, some have suggested that all of the studies that show effects are somehow flawed (Adair 2003). The alternative is that there are as yet not clearly defined biological mechanisms that have escaped scientific understanding. Of course, the lack of a full understanding does not make observed effects invalid. Such is the case, for instance, with EMF-mediated bone fracture repair, which is clinically effective but still not well understood (Aaron et al. 2004).

Published studies that have reported biological effects from exposure to weak ELF and RF fields are too many to mention individually. Effects in the ELF range include changes in enzymatic activity (Litovitz et al. 1997), teratogenic effects (Farrell et al. 1997), changes in gene expression (Lin et al. 1994), stress response effects (Lin et al. 1997, DiCarlo et al. 2002), and DNA damage effects (Lai and Singh 1997). RF effects include changes in enzymatic activity (Penafiel et al. 1997), memory effects (Lai et al. 1994, Wang and Lai 2000), and DNA damage effects (Lai and Singh 1996). There are also a number of experiments that show similar effects for both ELF and RF exposure indicating that common biochemical pathways may be involved in the response. These effects include changes in enzymatic activity (Penafiel et al. 1997), memory effects on rats (Lai et al. 1994, 1998) and effects on chromatin conformation (Belyaev et al. 2005).

While the evidence for biological effects from exposure to weak EMFs is extensive, it is important to point that a number of experiments have also reported null effects. Many of these are experiments that have attempted to replicate previously reported results (Desta et al. 1999, Cosquer et al. 2005). Such null effects bring into question either the validity of reported effects or the accuracy of replication conditions (Krause et al. 2004). The issue of replication was also evident in our own laboratory while studying teratogenic effects from ELF EMF exposure of chick embryos. Statistically significant effects were observed in some experimental campaigns but not in others even though experimental conditions appeared to be the same. The discrepancy in the results was eventually tracked down to a change in the chick progenitor flock. The unknown factor causing the variability in results was apparently a genetic factor (DiCarlo and Litovitz 1999).

The ability to examine experimental data to look for unknown factors usually requires that a large number of experiments be performed. More often than not this is not possible. The issue of experimental validity when exact replication is difficult to achieve can be best addressed using a suitable inhibition factor, if such a factor can be found. We have previously demonstrated in a number of instances, that in the case of exposure to weak ELF and RF EMFs, the inhibition factor is ELF electromagnetic noise (e.g., Litovitz et al. 1993, 1994, 1997b). The purpose of this paper is to show that the inhibiting ability of ELF noise covers a wide range of biological effects thereby suggesting that it might be a universal inhibition factor for EM induced biological effects.

Temporal characteristics of a bio-effecting stimulus

One of the issues concerning the general acceptance of experimental results that show effects from exposure to weak electromagnetic field is one of plausibility based on accepted demonstrable mechanisms. By one argument, weak EMFs do not carry sufficient energy to cause biologically significant interactions in the presence of local thermally driven electromagnetic noise. Calculations based on general physical properties of biological matter, which do not account for biological complexity, do indeed appear to demonstrate that local noise considerations make such interactions unlikely (Adair 1991, 2003). For interactions within the cellular membrane the magnitude of the local electromagnetic noise, thus calculated, is of the order of 500 V/m, which is many orders of magnitude larger than induced fields within humans from background ELF EMFs (< 0.001 V/m). Yet undisputable effects associated with research on bone fracture repair, which appears to be rooted in membrane bound interactions, have been observed with induced electric fields of 0.1 V/m or even less (Luben et al. 1982). This evidence suggests that thermal noise considerations are not sufficient to render certain effects implausible.

If we accept that certain bio-effecting interactions are possible, notwithstanding thermal noise considerations, then it is of interest to find alternate approaches to determine the viability of such interactions. Clearly, EMFs affect biological material at an elemental level, but beyond the obvious primary interaction the biological response is determined by the signal processing characteristics of the living biological entity. These characteristics are an inherent property of the living system defined by a complex transfer function, which if known, would predict what signals are filtered out and what signals are passed through. An important consideration in this simple model is how stimulating signal varies as a function of time.

The biological response to an environmental stimulus is a multi-step process involving a series of chained biochemical reactions characterized by varying rate constants, which form what is referred to as a signalling cascade. The net response results from the interplay of the biochemical events in the signalling cascade. This process, which incorporates the functions of signal detection and discrimination and control of the endogenous cellular reply, is referred to as signal transduction. A model system for the study of signal transduction is that of bacterial chemotaxis. This model involves two time-dependent processes that together constitute a rudimentary memory system. One is a fast process, occurring on a time scale of the order of 0.04s, which performs the function of measuring the concentration of chemotactant molecules through binding of these molecules to surface receptors. The other is a slower process, taking place on a time scale of the order of 5s, which performs a comparison function by modification of the receptors when no changes in chemotactant concentration are detected. This is a process of temporal sensing through which the bacterium makes continuous measurements of chemotactant concentration, compares successive measurements, and responds to the difference between them.

A model analogous to that of bacterial chemotaxis can describe the biological response to weak EMF exposure (Litovitz et al 1997a). The parameters of this model were determined in studies of the effect of EMF stimulation on ODC activity. A constantly applied 60 Hz EMF stimulus yielded a consistent doubling of the ODC activity. Changes in the ODC response were first examined by introducing zero-field gaps of varying duration in the exposure signal. It was determined that the magnitude of the response decreased as the frequency of the gaps increased. The full response was elicited when a field of constant intensity was applied, without interruption, for a minimum of 10s. The characteristic time associated with the response to this gapped stimulus was found to be 5s and was termed the memory time, τ_m . Knowing the requirements to elicit a full response, zero-field gaps were introduced periodically at 1s intervals for much shorter intervals that were increased until the response was negated. The magnitude of the response was found to decrease with increasing gap duration. No response was obtained when the gap duration was 100ms. The characteristic time constant associated with the response to this second gapped stimulus was found to be 0.05s and was termed the averaging time, τ_a . In essence these results showed that the ODC response to EMF stimulation involved two processes with rudimentary memory. Continuous measurements averaged over a time τ_a are compared successively. The response is elicited when a constant measurement persists over a time greater than τ_m .

The use of ELF noise to negate electromagnetic effects

The similarities of the temporal characteristics of the response to EMF exposure, as determined for the ODC model, with those of bacterial chemotaxis suggests that this may be a more general model applicable to the response to weak environmental stimuli. Furthermore, the requirement that certain temporal characteristics must be met to elicit a response suggests that strategies to alter the temporal characteristics of a stimulus could be devised for the purpose of negating the response. Such a scheme might be useful, for instance, for the mitigation of unwanted effects from EMF exposure.

The simplest strategy to alter the temporal parameters of an EMF stimulus is by the superposition of another EMF stimulus whose temporal characteristics do not meet the requirements to elicit a response. One such signal is ELF magnetic noise. Using the temporal sensing model with $\tau_a = 0.05\text{s}$ and $\tau_m = 5\text{s}$, it can be shown a noise signal with bandwidth in the biologically active frequency range below 100 Hz will not elicit a response. The superposition of a noise EMF stimulus over an existing stimulus results in a new stimulus which is noisy itself and is the sum of the local stimulus $s(t)$ and the superimposed noise $n(t)$. In order to fully negate the response $n(t)/s(t)$ must be greater than or equal to 1.

Measurements with the ODC model confirmed that the superposition of ELF noise could indeed negate the response (Litovitz 1994, 1997b). Other studies in our laboratory demonstrated that noise could also be used to inhibit teratogenic effects and effects on the stress response in chick embryos (Litovitz 1993, DiCarlo 1998, 1999b, 2000, 2002, Shallom 2002). Furthermore, it was also found that ELF noise could inhibit biological effects induced by mild mechanical vibration (DiCarlo 2002). Considered together this evidence makes a strong case for the argument that the inhibiting effect of ELF noise may be universal to weak stimuli.

Experiments carried out in other laboratories have also demonstrated the efficacy of ELF noise to inhibit both ELF and RF effects. Table 1 shows a list of published results that show the range of effects negated by the superposition of ELF noise. In the ELF domain effects elicited with field intensities between 1 μT and 400 μT have been blocked. In the RF domain effects from exposure to fields of the order of 1 to 3 W/kg have been negated. The lower intensity cases represent situations in which the viability of effects might be called into question based on thermal noise consideration. The thermal noise issue can still be a possible argument against viability in the higher intensity cases, but it is a less convincing argument particularly since equivalent field intensities have been demonstrated to be bio-effecting in bone growth stimulation studies (Luben et al 1982). The results of Table 1 show that the outcome of the observed response can be manipulated through the use of another stimulating agent of the same type as the bio-effecting agent, thereby lending credibility to the existence of such effects.

Table 1: Biological effects inhibited by the superposition of ELF noise

<i>Model</i>	<i>Exposure field</i>	<i>Effect inhibited</i>	<i>Reference</i>
Chick embryos	4 uT, 60 Hz sine	Two-fold increase/shift in ODC activity	Farrell et al. 1993
Chick embryos	1 uT peak, 100 Hz pulsed	Two-fold increase in developmental abnormalities	Litovitz et al. 1993
L929 cells	10 uT, 60 Hz sine	Two-fold increase in ODC activity	Mullins et al. 1993
L929 cells	10 uT, 60 Hz	Two-fold increase in ODC activity	Litovitz et al 1994
HL60 cells	6.7 uT, 60 Hz sine	40 % increase in c-myc transcript	Lin et al. 1995
Chick embryos	4 uT, 60 Hz sine	40 % reduction in the activity of 5'-nucleotidase	Martin et al. 1995
AMA cells	5uT, 50Hz sine	15% increase in cell proliferation	Rasmak et al. 1996
PC12 cells	8 uT, 60 Hz sine	15% decrease in intracellular dopamine	Opler et al 1997
L929 cells	835 MHz amplitude modulated, 2.5 W/Kg	40-100% increase in ODC activity	Litovitz et al. 1997
Chick embryos	4 uT to 10 uT, 60 Hz sine	Two-fold enhancement of survival of chick embryos in anoxic conditions by EM pre-conditioning	DiCarlo et al. 1999
Chick embryo	8 uT, 60 Hz sine 915 MHz CW, 1.7 W/kg repeated	27% decrease in HSP70 levels consistent with decreased cyto-protection	DiCarlo et al. 2002
Chick embryo	915 MHz CW, 1.75 or 2.5 W/Kg	Increase in HSP70 by preconditioning consistent with increased survival after hypoxia	Shallom et al. 2002
NIH3T3 cells	0.4 mT 50Hz	40% suppression in gap junction intercellular communication	Zeng et al 2002
Rats	2.45 GHz CW, 1.2 W/Kg	35% learning deficit	Lai 2004
NIH3T3 cells	0.2 mT 50Hz	50% co-suppression in gap junction intercellular communication with phorbol ester	Gao et al 2004
NIH3T3 cells	0.4 mT, 0.2 mT, 50Hz	30% suppression in gap junction intercellular communication	Zeng et al 2006

Discussion

In spite of hundreds of published results that claim the existence of biological effects from exposure to weak ELF and RF EMFs using a broad range of end points, there is still a great deal of uncertainty about whether these effects are real. Part of the problem is that effects have often been difficult to replicate and proposed biological mechanisms have not been substantiated and thus often remain speculative. But even when effects are generally accepted, a full understanding of the underlying biological mechanisms can still be lacking. Such is the case, for instance, in the case of EMF induced bone growth stimulation (Aaron et al. 2004).

Stimulation of living biological entities by weak exogenous stimuli involve signal transduction processes which often include signal integration and amplification. A model proposed in bacterial chemotaxis, which may apply to many other weak signal detection situations, assumes the existence of long-range cooperative interactions between receptors as a means to achieve signal amplification (Sourjik and Berg 2004). Other processes that could result in further signal amplification and discrimination are communication interactions between cells through gap junction channels. Direct cell to cell communication, evident in organized tissues and even in cell cultures as demonstrated by contact growth inhibition, is critical to bone-forming cells (Lecanda et al 1998). Biological effects could result from the disruption of any of the signalling pathways of the signal transduction process.

The biochemical basis for the interaction of EMFs with living entities is not clear. It is possible that the primary site of interaction is at the cellular membrane via modulation of receptor binding. If this were the case, a myriad

of downstream signalling pathways could be affected leading to observable effects. But the ability of noise to inhibit many of these effects provides a common link that sheds some light about the nature of the response. It is generally accepted that at a fundamental level the extent of the electromagnetic interaction is proportional to the intensity of the stimulus. As the intensity level increases direct heat dissipation resulting in measureable increases in temperature could be a consequence of the exposure. At such levels the superposition of a signal of equivalent intensity would only result in further heating. But at exposure levels for which heating is not an issue, such as the experiments listed in Table 1, the inhibiting ability of superimposed ELF noise indicates that these interactions are a signalling events with common temporal sensing characteristics. This also suggests that while the effects of EMF exposure may be evident in a multitude of observable parameters, it is possible that such responses might share a few key common biochemical pathways. The shared common pathways would be those that establish the signal averaging time, τ_a , and the memory time, τ_m of the temporal sensing process.

The evidence shown in Table 1 is suggestive of a general effect that may be universally applicable. This inductive conclusion would be difficult to prove for all cases. However, the fact that ELF noise inhibition has been effective in all instances in which it has been examined adds to the weight of the evidence supporting this argument.

Conclusions

A review of experimental results on the use of the superposition of ELF noise for the inhibition of effects induced by exposure to weak EMFs shows the efficacy of this technique to negate observed effects. These results apply to a broad range of end points and over a wide range of signal intensities suggesting that a common factor is at play. This common factor is likely to be a temporal sensing process characterized by two common rate constants. The broad scope of inhibited effects also suggests the applicability of the temporal sensing hypothesis as a general signal transduction mechanism for the interaction of EMFs with living systems.

Two general conclusions can be drawn from the foregoing review which shows that the superposition of ELF noise is an effective inhibiting factor in bioelectromagnetic effects: 1) the use of ELF noise in a pseudo-sham exposure condition would be beneficial in determining whether observed effects are attributable to EMF exposure, and 2) the superposition of ELF noise would be effective as a prophylactic means to inhibit unwanted biological effects in situations where exposure is unavoidable.

ELF and RF/MW Electric fields as bioeffectors: a much needed new direction in bioelectromagnetics?

ROGER COGHILL

For several decades now Western research attention in bioelectromagnetics has largely centred on the magnetic component of the electromagnetic wave. In their original 1979 paper, which some argue heralded much of the subsequent scientific interest, Wertheimer and Leeper concluded that the elevated incidence of childhood cancer near pole-mounted transformers in Denver was probably due to the magnetic field. Their conclusion was based on preceding research, which had reported magnetic field sensitivities of some animals and fishes. Savitz et al. later attempted to include electric field measurements in their replication of the Denver study, but abandoned their effort through an inability to address the topic of chronic exposure. It may have escaped the notice of both authors that pole mounted transformers inevitably generate large electric fields in converting the primary to the secondary induced voltage. Moreover, electric fields (unlike magnetic) are present wherever there is connection to the main supply, so the electric component was actually an equal candidate for Wertheimer and Leeper's speculations.

The world's power utilities have also favoured magnetic field research, comforted by the recognition that few homes will experience the 0.4uT commonly used as a cut point in epidemiological studies to define relative risk. The popular EmDEX probes (designed for EPRI) indeed do not even permit the user to collect electric field data without elaborate engineering modification.

Eastern bloc countries do not share this view, arguing that mankind has always had evolutionary experience of magnetic fields, in that we all live on the large magnet of the Earth.: and if anything new has occurred on the planet since the advent of electricity then it is the alternating electric field, for which there is no evolutionary counterpart (Shandala et al, 1988). The search for a mechanism of interaction incorporating the magnetic field only has proven inconclusive to date despite the evidence of many non thermal effects. It might therefore be more fruitful to reappraise the role of the electric component.

Out of eight published domestic epidemiological studies of the electric field only three took proper measurements, and these together offer strong support for the electric field at the nocturnal bedplace as the active parameter (see Table 1). The remaining five used spot or portable probes, or room centre measurements which do not adequately characterise bedplace exposure (see Table 2). The three pertinent studies show a consistent dose response pattern indicating that chronic exposure to ELF electric fields above 20V/m are hazardous to child health.

Table 1: Bedplace ELF electric field exposure in childhood cancer homes

Study	Exposure measures	Odds ratio (OR) or relative risk (RR)	95CI%
Coghill, Steward et al, 1996	12 hours TWA, bedplace only	4.69	1.17-27.0
Dockerty, Elwood et al, 1997	24 hours TWA, bedroom and one other room	2.3	0.4 – 12.7

- abandoned a third way through the collection

Our laboratory has recently reported that ELF electric fields at levels commonly seen near powerlines and domestic electric appliances can create nitrites in aerated distilled water to a concentration reported by other studies to cause ill health. The effect is robust over many experiments. This simple physico-chemical effect (paralleling the effect in respiring organisms largely composed of aqueous solutions) may explain the thirty year old mystery of how such weak fields can cause ill health in the absence of heating.

Other studies show that many of the disorders associated with chronic ELF EM field exposure are also associated with excess nitrites found in the patients biological fluids. In childhood leukaemia for example the nitrite level is four times normal in serum and two orders of magnitude higher than normal in the CSF.

An appraisal of the literature as presented in this paper offers the conclusion that more research attention should be paid to electric fields and this in turn may lead to new standard setting which recognises at last the importance of non-thermal effects.

EFFECT OF LOW POWER MILLIMETER WAVES IRRADIATION ON $C_{12}EO_5/H_2O$ MEMBRANE MODEL: A 2H -NMR SPECTROSCOPY INVESTIGATION.

Abstract

The influence of low power millimeter wave (MMW) irradiation in the 53.57-78.33 GHz frequency range, on water molecules of a model membrane has been investigated by Deuterium Nuclear Magnetic Resonance (2H -NMR) Spectroscopy. The quadrupole splitting (Δ) of deuterated water within the lamellar mesophase of the $C_{12}EO_5/H_2O$ binary system has been measured, at 25°C constant temperature. It has been found that continuous wave (wide band 53.57-78.33 GHz) irradiation of the above membrane model system produces, a significant increase of the quadrupole splitting of deuterated water molecules. The observed variation of the Δ for heavy water is opposite with respect to a temperature increase and it depends on the level of hydration of the lamellar sample: in samples with an higher water content, MMW irradiation produced a larger Δ increase. The observed effect was totally reversible. In few hours the splitting came back to the initial value. We propose an explanation in terms of variation of the free/bound water population ratio and calculate the change in the Gibbs free energy of the system after the irradiation treatment. The interaction model membrane-MMW, might involve the structures that liquid water can adopt by using hydrogen bonds.

Short running title: millimeter wave effect on membrane hydration

Key words: membrane hydration; low power millimeter waves; 2H -NMR spectroscopy

Introduction

The interaction between low power millimeter waves (power density below 1 mW/cm²) and biological systems, concern either the effects induced by this radiation on the systems, or the basic mechanisms of interaction. In 1968 Webb and Dodds observed the inhibitory effect of MMW on the growth of the *E. Coli* bacterium [Webb, 1968]. Afterwards H.D. Devyatkov [Devyatkov, 1974, 1981, 1983] and other Russian scientists [Sevastyanova, 1974, 1981] observed the influence of such radiation on various biological systems. Interesting studies on the growth of *Saccaromices cerevisiae* were performed by Grundler and Keilmann [Grunder, 1977, 1978, 1983]. A review of the most important results, in which some physical-chemical aspects of the MMW-biological systems interaction are also reported, is due to Pachomov et al. [Pachomov, 1998]. The effects observed on MMW irradiated cell systems go from cell growth variations, to changes in DNA morphology [Brill, 1993]. Ionic membrane transport alterations were also reported [Brovkovich, 1991, Geletyuk, 1995, Kataew AA, 1993]. Since 2002, we have shown that low power (<10 mW/cm²) electromagnetic radiation, in the millimeter wavelength range (3.84-5.78 mm), could be used as a physical mean in order to influence the proliferative behavior of several cultured cells [Chidichimo, 2002]. It should be highlighted that the proliferation rate of the investigated tumoral systems was inhibited by MMW in certain exposure conditions, whereas that of the healthy cell systems was not. Moreover, we have also shown that the frequency of the radiation and the irradiation time [Beneduci, 2005a] influence the observed effects. Besides the effect on cell proliferation, significant morphological alterations were observed on human melanoma, breast carcinoma and erythromyeloid leukemia cells [Beneduci, 2005a,b, Beneduci, 2006].

Until now however, there is not a generally accepted point of view on the biophysical mechanism of interaction between millimeter radiation and biological systems. Besides thermal effects that occur at high powers (>10 mW/cm²), it was hypothesized that the MMW-biosystems interaction could involve resonant nonthermal mechanisms at very low powers [Fröhlich, 1968, 1977, 1980, 1983, 1986a, b, Kaiser, 1988, Sinizin, 1998;]. Data on the dielectric properties of water [Ellison, 1996] and of biological systems [Schwan, 1983, Grant, 1984] agree on the fact that water is the only molecular system, able to directly interact with electromagnetic waves in the millimeter range above 1 GHz [Beneduci, 2006].

However, besides the direct field effect on water dipoles, any biological effects could be explained only if the electromagnetic field affects the reaction sensitivity of some cellular processes, that is crucially determined by the reaction moments [Neumann,2000].

The absorption of microwave radiation by water molecules may induce changes in the equilibrium free water/bound water involved in several cellular processes in which a chemical control is exerted [Neumann,2000]. Water plays also crucial roles in proton transfer reactions and in transport processes through narrow channels or pores in which water molecules assume particular interfacial orientations [Neumann,2000]. The millimeter radiation could affects the orientational dynamics of water molecules in such systems, causing several bio-effects.

The above considerations and the morpho-functional alterations of the membrane observed on some *in vitro* cultured tumoral cells after MMW irradiation [Chidichimo 2002, Beneduci 2005b, Beneduci, 2006, Szabo 2006, Chen 2004], brought us to begin the study of the MMW-membrane interaction.

The present work therefore, deals with some aspects of the physico-chemical mechanisms that occur when a model membrane system interacts with the millimeter waves.

All the biological membranes exist because of the intermolecular forces occurring between the components of the system (hydrophobic interactions, dipole-dipole, ion-dipole, hydrogen bonds network). The water molecules interacting with the polar head groups of the anfiphilic molecules by non-bonding forces are in chemical equilibrium with those ones that constitute the bulk water and are the so called “free water” molecules. A general reaction step that summarizes such type of chemical process occurring at the polar interface of a double layer is the following:

where $S(H_2O)_r$ is the amphiphilic molecule that binds r water molecules and being in thermodynamic equilibrium with the species $S(H_2O)_{r+1}$ that bind $r+1$ water molecules, $(n-1)H_2O$ being the free water molecules. The model membrane system investigated in the present work was the penta(oxyethylene)-dodecylether/water lamellar lyotropic-liquid crystal system, which has been extensively studied in the past [Mitchell, 1983, Dimitrova et al., 1996,]. Such binary system was conveniently adopted by us because it easily forms double layer of lamellar structures (like biomembranes), at room temperature in a relatively wide range of compositions.

If a model membrane is made by using heavy water (2H_2O) instead of ordinary water (H_2O), one can record a deuterium NMR spectrum which will be the result of a superposition of spectral doublets whose peak separation (in Hz) depends on the orientation of the double layer (lamella) with respect to the NMR static magnetic field [Pake 1948]. When the plane of the lamella is oriented parallel to the static magnetic field, the peak separation is called quadrupole splitting, Δ .

In the case under study, the $C_{12}EO_5/^2H_2O$ system, Δ is proportional to the total fraction of water molecules bound to the polar head group of the surfactant, p_b , and to an average order parameter S_b that brings information about the local motion of the O-D bonds in heavy water:

$$\Delta = \frac{3}{4} \nu_q p_b S_b \quad (2)$$

where, ν_q is the quadrupole coupling constant. The equilibrium reaction that concern the hydration process of the surfactant molecules in the lamellar structures, could be written in the general form (3) [Mitchell et al., 1983], where S_f are the free surfactant molecules, W_f the free water molecules, $S_b(W_b)_r$ are the complexes formed by a surfactant molecule and r water molecules and K_b is the thermodynamic equilibrium constant.

It is clear that any cause affecting the free/bound water equilibrium must reflects a change in the value of the quadrupole splitting that can be conveniently measured by the 2H -NMR technique [Mitchell et al., 1983].

Materials and methods

Deuterium NMR spectra were recorded on a 300 MSL Bruker spectrophotometer operating at 46.053 MHz deuterium resonance frequency, using a 10 mm tunable probe. To record the spectra, samples were introduced in a 10 mm NMR tube. Each spectrum is the Fourier transform of a FID obtained integrating 400 scans, with a 1 sec repetition time. Each scan is a quadrupolar echo pulse sequence, with a 9 μs 90° pulse and a 88 μs delay time. Sample temperature was constantly maintained at 25°C by the spectrophotometer variable temperature controller VT 1000.

Chemicals

Normaldodecylpentaoxyethylene ether ($C_{12}EO_5$) was purchased from Sigma-Aldrich (99% purity) and deuterated water from Cambridge Isotope Laboratories, Inc. (99.9% purity). Both chemicals were used without

further purification. Lamellar lyotropic liquid crystal samples, $C_{12}EO_5/^2H_2O$, were prepared by weight adding the right amount of heavy water to the surfactant placed in a 5 mm NMR tube. The mixtures were then warmed up and vortex stirred to achieve homogeneity. Three samples were prepared containing 30% (sample A), 25% (sample B) and 20% (sample C) by weight D_2O . A 4 mm glass bar was introduced inside a 5 mm NMR tube to obtain a thin layer (0.5 mm) of lamellar phase (fig.1). Samples were then sealed and stored at 25°C for about three days.

Experimental MMW facilities and sample irradiation

The MMW radiating apparatus AMFIT 32 (made in Russia by the UWOM company of Nizhny Novgorod), was used as radiation source. It is a microwave noise generator diode, able to supply a 53.57-78.33 GHz frequency band at a global mean power density $< 1 \mu\text{Watt}$. Samples were placed at the end of the conical antenna of the instrument and were irradiated for 7 hours. Temperature was strictly controlled and maintained at 25 °C along the experiment. Samples were weighted after the irradiation treatments to check for evaporation of water but weights remained constant.

Fig. 1. Schematic representation of the lamellar sample and of the irradiation geometry (not in scale).

Results

Stability of the system under constant temperature condition

Prior to perform any irradiation experiment, the stability of the lamellar samples was tested under 25°C constant temperature condition. In fig. 2, the variation (%) of the quadrupole splitting is showed for a time course of 4 days, in the case of the sample A. It could be noted that Δ resulted very stable showing only restricted oscillations of the order of $\pm 0.25\%$ ($N=96$), around the equilibrium Δ value. These random variations could be attributed to small fluctuations of the temperature of the thermostated chamber (probe). Analogous behaviour was observed for the other samples B and C (data not shown).

Quadrupole splitting behavior of heavy water under MMW irradiation

Typical 2H -NMR spectra recorded before and after three irradiation treatments, were reported in fig.3 **A**, **B** for sample **A** and **B**. Significant increases of $5.3 \pm 1.0\%$ ($N=3$) and $2.6 \pm 0.5\%$ ($N=3$) of the quadrupole splitting of heavy water, were observed in the irradiated samples **A** and **B** respectively. A negligible perturbation of the Δ , was also observed in the irradiated sample **C** (data not shown).

Fig. 2. Sample A before irradiation. Quadrupole splitting variation of $^2\text{H}_2\text{O}$ as a function of time ($T=25^\circ\text{C}$). Spectra were recorded along 4 days with 1 hour steps. The sample is very stable.

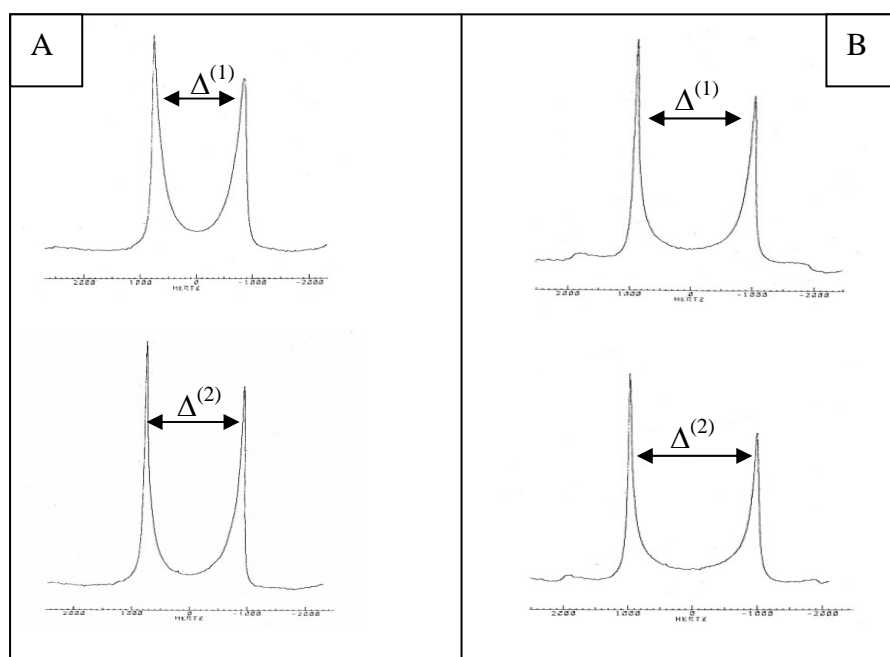

Fig 3. $^2\text{H}_2\text{O}$ -NMR spectra of the investigated samples. The Δ of heavy water in sample A ($\Delta^{(1)}=1608$ Hz) gained 80 Hz after the irradiation ($\Delta^{(2)}=1688$ Hz). The increase of the Δ for the sample B was 45 Hz ($\Delta^{(1)}=1918$ Hz; $\Delta^{(2)}=1963$ Hz).

The observed variations are very far from those which could be induced by thermal fluctuations. Actually, from control sample data, we have seen that thermal fluctuations (of less than 1 degree) caused statistical random variations of the quadrupole splitting about the equilibrium value at 25°C , which were not larger than 4 Hz (0.25%).

Fig. 4. Sample A. Variation of the splitting value in percentage as a function of temperature. The point zero on the ordinates corresponds to 25 °C.

²H₂O quadrupole splitting temperature dependance

In fig.4 the variation of the quadrupole splitting of heavy water relative to sample A was shown as a function of temperature, in the range 9°C – 41°C. The thermal process, from 9°C to 41°C, is reversible (see upfacing triangle in fig. 4). At this point, two fundamental findings have to be underlined: 1) to produce a 6% increase in Δ in such a system (sample A), equal to that observed under MMW irradiation, it was necessary to reduce the temperature of the system of about 15°C. 2) MMW irradiation produced an increase of Δ while a temperature increase produced a Δ decrease. This temperature dependence was similar for the other two samples (B and C), as previously reported [Rendall K, 1984].

MMW irradiation increases membrane hydration

In view of equation (2), the quadrupole splitting (Δ) can change only if p_b and/or S_b changes. Summarizing the results, the variation of the quadrupole splitting of D₂O contained in the irradiated model membranes, increases as the percentage of heavy water within the samples increases. Going from the less hydrated (C) to the more hydrated system (A) the free water dispersed between the surfactant lamellae gradually increase. Hence a crucial parameter influencing the variation of Δ after MMW irradiation, must be the amount of free water present in the system. More precisely, we observed that the effects produced on the quadrupole splitting of heavy water by the MMW irradiation increases as the free water/ bound water (p_b) ratio increases. A variation of only the order parameter S_b cannot explain the observed trend. Indeed, such a parameter reflects the local orientational order of the bound water. Thus the value of S_b depends on the mobility of water molecules linked to the surfactant polar heads. If the MMW irradiation had acted on this physical property of the system, the variation of Δ should not depend on the sample composition. Thus, we interpreted our experimental findings, identifying a primary interaction occurring between the millimeter radiation and the free water of the membrane system that strongly absorbs the MMW. As first order effect, consequence of such direct interaction, is the shift of the thermodynamic equilibrium (3) towards right. Hence, the membrane resulted more hydrated (greater p_b values) after the MMW irradiation treatment, than the equilibrium initial condition. Such fundamental perturbation was observed as a quadrupole splitting increase. In thermodynamic terms, this means that the Gibbs free energy variation relative to the process (3), expressed by equation (4) is shifted towards more negative values (more favoured thermodynamic process) by millimeter wave irradiation.

$$\Delta G = G_{w_b} - G_{w_f} \quad (4)$$

The first term (G_{w_b}) of eq.4 is the Gibbs free energy of a mole of bound water molecules. Its value depends on local thermodynamic properties of water molecules bound to the polar heads of the surfactant, that are not susceptible to change under irradiation. Then, G_{w_b} does not change. Hence we can write equation (5)

$$G_{w_b}^{(1)} = G_{w_b}^{(2)} \quad (5)$$

where the superscript (1) and (2) refer to the state of the system before and after MMW irradiation, respectively.

Variation of the Gibbs free energy of the system under MMW Irradiation

We derived the change in the Gibbs free energy variation of the system produced by MMW (ΔG_{MW}). Using equation (4), the equality (5), and defining the states of the system before and after irradiation by the superscript (1) and (2) respectively, we can write the following equations:

$$\Delta G^{(1)} = G_{W_b}^{(1)} - G_{W_f}^{(1)} = -RT \ln K_b^{(1)} \quad (6)$$

$$\Delta G^{(2)} = G_{W_b}^{(2)} - G_{W_f}^{(2)} = -RT \ln K_b^{(2)} \quad (7)$$

We can express thus, the quantity ΔG_{MW} as the difference between the Gibbs free energy variation relative to equilibrium (3) before and after irradiation:

$$\Delta G_{MW} = \Delta G^{(2)} - \Delta G^{(1)} = -[G_{W_f}^{(2)} - G_{W_f}^{(1)}] \quad (8)$$

Equation (8) tells us that energetic changes of the state of the system, produced by MMW irradiation, are due to changes, opposite in sign, in the energetic state of free water present in the system.

We can correlate the quantity ΔG_{MW} with the thermodynamic equilibrium constant K_b relative to process (3) before and after MMW irradiation:

$$\Delta G_{MW} = -RT \ln \frac{K_b^{(2)}}{K_b^{(1)}} \quad (9)$$

In table 1, quadrupole splitting experimental values and calculated thermodynamic data relative to systems **A**, **B**, and **C** were collected.

The p_b values were determined by means of equation (2) and using the S_b value as reported by Mitchell et.al. The increase of the Gibbs free energy of free water, produced on the systems after irradiation, is greatest for sample **A** (+2882 J/mol). Consequently, equilibrium (3) is shifted towards the water-surfactant complex ($K_b^{(2)}$ 3.2 fold greater than $K_b^{(1)}$ after irradiation). This effect is less pronounced in system **B** (+834 J/mol; $K_b^{(2)}$ 1.4 fold greater than $K_b^{(1)}$ after irradiation). No net increase was observed in system **C**.

Table 1

State of the System	Δ (KHz)	p_b	S_b	$K_b^{(2)} / K_b^{(1)}$	ΔG_{MW} (J)	$C_{12}EO_5/H_2O$ % (w/w)

Table 1. Experimental and calculated data of the parameters characterizing the lamellar system. Low power MMW irradiation induces an increase of the fraction of water molecules bound to the surfactant. See text above for details.

Summary

The quadrupole splitting of deuterated water of a $C_{12}EO_5/H_2O$ membrane model was measured by 2H -NMR spectroscopy. By irradiating the model membranes utilizing low power millimeter waves (wide band 53.57-78.33 GHz, continuous wave), we modified (increase) the splitting value of the heavy water. This cannot be explained in terms of solely provided heat. In fact, raising temperature produces an opposite behaviour of the monitored parameter (splitting decrease). Weighting the samples after millimeter waves exposure, allowed us to be sure that water did not evaporate. We also found that the effect is completely reversible after few hours. Furthermore, the most hydrated samples were more sensitive to the irradiation treatment. Making some assumptions we propose that the MMW interact primarily with the free water trapped between the layers of the system, inducing the water molecules to bound the surfactant. Literature data and studies we are carrying out on the dielectric constant of both normal and deuterated water (data to be published), strongly indicate that water is the primary absorber of the millimeter wavelengths and the obtained dielectric data are different for the two kind of water at the same frequencies. Works in progress are clearly indicating that very likely the structures that water can adopt by means of hydrogen bond network play a central role in the observed effects; phospholipid model and in vitro cultured cells, respond to some specific frequencies rather than others.

UNIVERSITY OF ROME “TOR VERGATA”, ROME, ITALY
(volpe@bio.uniroma2.it)

Abstract. This contribution points to the mechanisms of zero-frequency (DC) and oscillating (AC) magnetic field (MF) bioeffects. The survey pays particular attention to the action of artificial MFs not only at the ionic, molecular or macromolecular levels, but also at the levels of *in vitro* cycling cells, *in situ* functioning tissues or organs and total bodies. The significance of crucial findings concerning the MF-dependence of cell proliferation vs. cell death, extent of necrosis vs. apoptosis and cell membrane fluidity is judged by comparing the results obtained in a solenoid (SLD), where an MF can be added to the geomagnetic field (GMF), with those obtained in a magnetically shielded room (MSR), where the MFs can be partially attenuated or null. This comparative criterion is required because the differences detected in the experimental samples against the controls are often rather small *per se*, as observed in estimating the MF-dependence of expression of single genes or of the rates of total DNA replication, RNA transcription and protein translation. The analysis also considers the MF-dependence of the interactions between host eukaryotic cells and infecting bacteria. In the framework of studies on the origin and adaptation of life on Earth, theoretical insights paving the way to elucidate the mechanism(s) of MF-interaction with biostructures and biosystems of different orders of organization are considered.

Introduction

Since life on Earth originated in natural MFs, while a large part of the living matter became subjected to artificial MFs only in the XXth Century, a question concerning the adaptation of organisms to these new unexpected fields emerged. For instance, would an animal maintain the normal ontogenesis in an artificial MF characterized by an amplitude much greater than that in which it evolved?

In recent years, the number of reports posing this question has increased. In particular, the epidemiological aspect was debated with emphasis since the negative effects of extremely low frequency (ELF) MFs generated by 50 Hz high voltage power transmission lines, video screens, electric blankets or other home appliances, was forcibly denounced as time went by [1]. The belief that the field intensity was rationally fixed below a risk threshold functioned as objection to the alarm. However, the available data were contradictory [2]. On the one hand, a benefit from the low-energy pulsed MFs in non-union bone fracture healing and in cell regeneration was reported [3]. On the other, the influence of MFs at 50-60 Hz exerted on the nervous system [1] induced preoccupation.

In any case, the MFs showed a distinct influence on cell proliferation (Figs. 1 and 2) [4] and on the role of the calcium ions in the transduction of this influence [5-10]. In particular, it was reported that a 22 μ T MF at 60 Hz modulated the calcium influx [8]. The MF-dependence of the state of the cell membrane was studied through microscopy [11] and cytofluorimetry [12]. The influence of 1-10 μ T MFs at 50 Hz on the membrane conductivity and permeability was taken into account [11]. A study was performed on the effects of very weak MFs (10^{-6} to 10^{-5} T) on chicken embryogenesis [13]. The results of this investigation were confirmed in some laboratory conditions [14] and contradicted in others [15,16].

The divergences encountered in the literature with respect to the MF-dependence of certain biological structures and functions are not due only to the differences of equipment facilities or experimental accuracy, but rather to the adequacy of proposed methodological approaches. In addition, there is still a largely recognized lack of theoretical analysis to explain the mechanisms which underlie the interactions between the MFs and the various cellular targets. Thus, the main aim of this report is to draw the attention on the efforts that have been made to define the basic physical laws describing MF-biosensitivity.

Fig. 1. Acceleration and deceleration of cell proliferation after addition or subtraction of MFs [4]. Cultures of *Friend erythroleukemia* cells were left to grow in parallel for about 100 hrs: (a) under the control 45 μ T DC of the Earth's MF, (b) in an LSD where 70 μ T at 50 Hz were added to the 45 μ T DC of the Earth's MF and (c) in a MSR where the highly attenuated field essentially reflected the residual 20 nT DC of the Earth's MF and the 2.5 pT AC of the power line MF (in the MSR the 45 μ T DC of the Earth's MF was attenuated 2500 times at 0.0 Hz because the AC shielding factor was estimated to be about 2500 for frequencies between 0.001 and 10000 Hz, while the applied AC MF was 30000-40000 times smaller at 50 Hz). The results represent the mean of five experiments for (b) vs. (a) and three experiments for (c) vs. (a). The Student's paired *t* test showed *P* values of 0.02 for both (b) vs. (a) and (c) vs. (a).

Is the question of the mechanisms of magnetic-field bioeffects still open?

Following the well known contributions of several laboratories which attracted the attention of the scientific community on the possible involvement in MF bioeffects of resonance at the cyclotron frequency under the combined influence of DC and AC MFs [17-20], Blanchard and Blackman [21] tried to enrich the Magnetobiology with a theory based on an ion parametric resonance model.

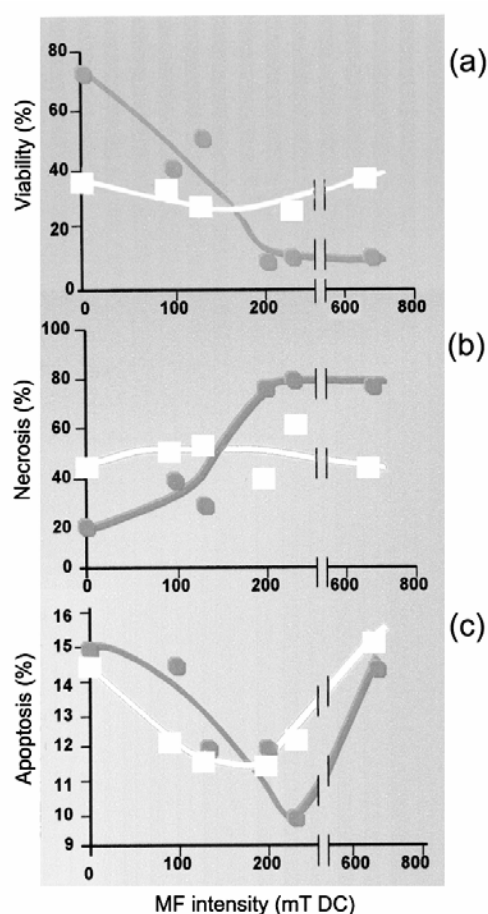

Fig. 2. Dependence of the human macrophage viability, necrosis and apoptosis, in the absence and in the presence of mycobacterial infection, upon static MFs [39,40]. Macrophages (MDMs), separated from PMB cells attached for 1 hr to the bottom of a flask, were subdivided, using dishes, into a number of equal samples each consisting of $1 \cdot 10^6$ MDMs in 1.5 ml of RPMI-1640 medium. Five samples were maintained for 5 days under DC MFs of various intensity, while a control sample was kept in the absence of any MF. At the end of the fifth day of exposure, each sample was washed twice with PBS, while the MDMs were detached from their dish, treated with PI and analyzed cytofluorimetrically. A parallel set of samples (each also consisting of $1 \cdot 10^6$ MDMs in 1.5 ml of RPMI-1640 medium), after a 5-day permanence in culture without MF, was infected with *Mycobacterium tuberculosis* (MTB) and maintained for another 2 days under the same MFs of various intensity (a control MTB-infected MDM sample was kept for 2 days in the absence of any MF). At the end of the second day of exposure, each MTB-infected MDM sample was washed twice with PBS, detached from the dish bottom, treated with PI and analyzed cytofluorimetrically. (a) Viability of the uninfected MDMs vs. that of the MTB-infected MDMs; (b) necrosis of the uninfected MDMs vs. that of the MTB-infected MDMs; (c) apoptosis of the uninfected MDMs vs. that of the MTB-infected MDMs. (λ-λ) Uninfected MDMs; (ρ-ρ) MTB-infected MDMs. The values represent the mean of three experiments, each performed in triplicate. The Student's paired *t* test showed *P* values of 0.04 for (a), 0.01 for (b) and 0.05 for (c).

Anyway, from a unifying physico-chemical point of view and despite the list of MF bioeffects reported earlier, the research is still unable to provide a proper explanation. For this reason, it is convenient to re-

consider, in detail, other contributions which could make the efforts more circumstantiated and allow a comprehensive theory of the MF bioeffects.

Long ago, it was suggested that the rise of a ponderomotive force caused in a biostructure by non-uniform static MFs could lie on the basis of the magnetotropism of plants, where the "paramagnetic cells" representing a minor biomass, would be forced towards a point of maximal field while the "diamagnetic cells" representing a major biomass would be forced towards the opposite direction. Studying the interaction of the neuromembrane ionic channels with the spreading action potential, Volobuev and Coworkers [22] proposed that "external" MFs interact with hypothetical "internal" MFs created by the ionic channels and nodes of Ranvier. This could explain the decrease observed in the speed of propagation of the action potentials in static MFs. Another study by Agulova and her Colleagues [23], concerning the behaviour of non-equilibrium systems in low-frequency/low-intensity MFs, distinguished the direct perception of the MF by biomolecular structures from the signalling role of the MF through the central nervous system.

Fig. 3. *Stability of the rates of DNA replication in Friend erythroleukemia cells after their long exposure to an AC MF* [42]. The cells were pre-exposed to 70 μ T at 50 Hz plus 45 μ T DC of the Earth's MF for 318 days, during which they were necessarily reinoculated into a fresh medium twice per week (during each reinoculum, the cells remained in the absence of irradiation for 20 min). Then, two samples were inoculated at a density of $0.3 \cdot 10^6$ cells/ml and followed during their culture growth cycle. At intervals of 24 hrs, $2 \cdot 10^6$ cells were incubated in 2 ml of the same medium in which they grew (containing ten per cent foetal calf serum) with 2 μ Ci of [3 H]thymidine (86.1 Ci/mmol). The incubation lasted 50 min at 37 °C under shaking, in the absence of 5% CO₂ in air. The labelled cells were washed three times with PBS (without Ca²⁺ and Mg²⁺), harvested and treated with 1 ml of 10% TCA at 4 °C for 1 hr. The TCA-precipitable material was loaded through a 0.45 μ m Millipore filter and washed twice: first, with 15 ml of cold 5% TCA and, second, with 5 ml of 70% ethanol. The yielded sediment was dried at 20 °C and introduced into 10 ml of Ultima Gold scintillation liquid to measure its radioactivity. (μ - μ) Cell proliferation outside the SLD under the sole 45 μ T DC of the Earth's MF; (λ - λ) cell proliferation inside the SLD under 70 μ T at 50 Hz plus 45 μ T DC of the Earth's MF. The experiments were repeated three times. The Student's paired t test showed P values of 0.06.

They noted an influence of the GMF variations on the precipitation and agglutination reactions in aqueous solutions and on the Piccardi test [24]. Kislovsky [25], in an attempt to explain the biovariations caused by GMF perturbations, suggested the occurrence of dissipative clathrate structures in the aqueous medium and on its borders in non-equilibrium conditions. The length of conservation of these structures was taken as an example

BIOLOGICAL COMPLEXITY AND MAGNETIC-FIELD SENSITIVITY

of near-critical phenomena that are close to the temperature of phase transitions of the second kind: liquid-liquid. In such a case, the phase transitions would be at the lower critical temperatures of stratification of the aqueous solutions, when the elements of short-range order inherent in clathrate structures are abolished.

Zhvirlis [26], being interested in the influence of solar activity on the biosphere, paid attention to the correlation of some medico-biological tests with the index of GMF perturbation, in which sector boundaries of the interplanetary MF, associated with the solar wind, were taken as zero. This study revealed that the direction along the phase trajectory contour changed when the Earth crossed the sector boundary. Vladimirsky and Temurjants [27,28], on the basis of the fact that the Piccardi test was sensitive to the polarity of a radial component of the interplanetary MF, supposed that this sensitivity could be due to the geomagnetic micropulsations in the range from 0.007 to 0.1 Hz. Therefore, they presented a list of principles concerning the influence of weak ("non-thermal") and ultraweak ("natural") AC MFs on inorganic and biological systems.

In contrast with the opinion of Binhi [29] who considered the nuclear magnetic resonance as impossible in biological magnetoreception, this list re-encouraged the idea of a possible role of nuclear magnetic resonance in the GMF variations. Hence, Lednev and Coworkers [30] suggested that the calcium-binding proteins constitute the place of primary action of combined MFs. In their opinion, these proteins cause a splitting of energetic levels of the calcium ion oscillation in the protein (*Zeman effect*) while the width of the splitting is equivalent to the cyclotron frequency of calcium and the applied DC MF. On this basis, the parametric resonance was thought as a mechanism for increasing ionic energy. Moreover, the same Authors proposed that DC, AC and combined DC+AC MFs can change the polarization degree, while the biological effects of the MFs can be induced by the same polarization degree of the calcium ion oscillation.

Binhi and Coworkers [31-33] studied the mechanism of the magnetosensitive ion binding by proteins, under the influence of external AC MFs, in the framework of an idealized quantum model. It turned out that the dissociation probability of an ion-protein complex depends on frequency and amplitude. This was shown to be a consequence of the interference of angular modes of the ion wave function.

Moreover, attention was drawn on the problem of the dielectric response of some biological tissues [34] (in relation with the orientation, in a DC MF [35], of ions, molecules and cells), while Zhadin [36] investigated the thermal oscillations of the calcium ion in a calcium-binding protein, under the influence of combined DC+AC MFs. From the study it emerged that the DC MF causes the Larmor precession of ion oscillations. Since the cyclotron frequency is twice the Larmor frequency, this led to the suggestion that the phenomenon could serve as a basis for increasing the kinetic energy of the calcium ion due to parametric resonance. In harmony with this suggestion, an AC electric field perpendicular to a DC MF (or an AC MF parallel to a DC MF) was expected to increase the ionic energy while a maximal effect was expected at the cyclotron frequency of an AC MF.

Zhadin [36] tried to solve equations of motion of the ion in a macromolecule under the influence of the MFs, considering the damping effects and the influence of particles surrounding this ion. In contrast with Lednev and Coworkers [30] and Blanchard and Blackman [21], he showed that the possibility of parametric resonance is not credible for the AC MF frequencies, being many orders of magnitude lower than the natural frequency of an ion in a macromolecule. Indeed, resonance-like phenomena were found to be induced by the influence of a DC MF alone and by a combined DC and AC MFs without any parametric resonance. Zhadin [36] estimated that the MFs may cause changes in energy of the ionic thermal motion which, in turn, would be sufficient to trigger variations in the conformational state of a macromolecule.

Does the MF-effect depend upon the complexity of given biostructures or biosystems?

The debate was focused on the theoretical basis of the MF-action on macromolecules (Fig. 3): on the one hand, it was suggested that weak extremely low-frequency MFs affect intracellular DNA directly, since the MFs must exert a force of the order of $I_{\text{DNA}} = 1.6 \cdot 10^{-13}$ A on the currents that flow in the DNA [37]; on the other, it was claimed that this conclusion is not in agreement with physical principles, since the force on the current carrying strands generated for example by a MF, $B = 5$ μ T, would be extremely weak, i. e. equal to $F = BI_{\text{DNA}} = 8 \cdot 10^{-19}$ N/m [38]. In other words, a motion of a 1 mm long strand through a distance equal to that of the strand diameter of 2 nm represents an energy of $1.6 \cdot 10^{-33}$ J or $3.7 \cdot 10^{-13}$ kT (hence, the energy transfer from the action of the MF on the strand would be negligible compared to the energy of thermal agitation).

Whatever the conclusion of the debate will be, several years ago we suggested that, at variance with the influence of a weak AC MF on cell-cycle kinetics [4] and cell membrane fluidity [12], this field is insufficient to exert an appreciable influence on macromolecular biosynthesis [41]. This was also in harmony with recent studies concerning, on the one side, the genome stability *vs.* deprivation or enrichment of the GMF [42] and, on the other, the gene expression in a Space-simulating magnetically shielded environment [43].

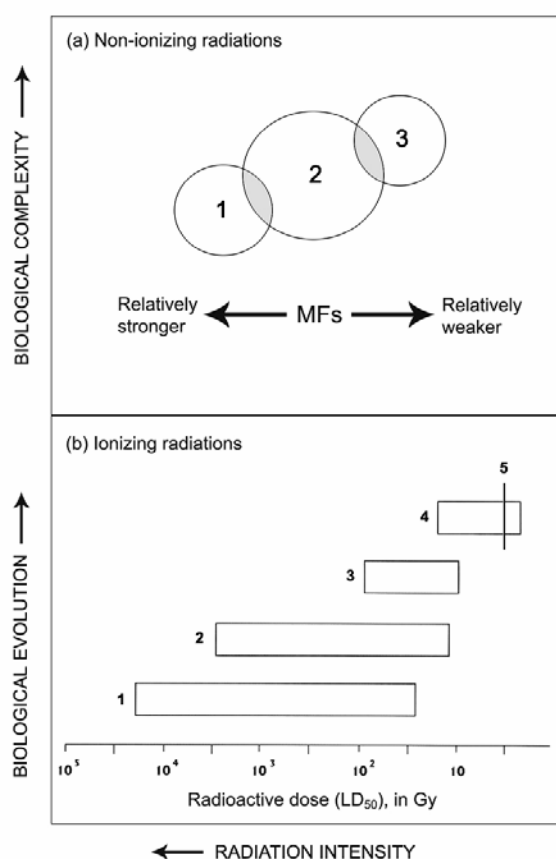

Fig. 4. *MF-sensitivity as a function of complexity of the irradiated biological target.* (a) Orders of organization of biostructures or biosystems invested by non-ionizing radiations: 1. molecules and macromolecules; 2. biostructures; 3. biosystems. The size of the areas reflects the results of 100 experiments, estimated from the literature, performed by using DC MFs for about 30% and AC MFs for about 70%. (b) Evolution of biosensitivity to ionizing radiations [85]: 1. bacterial cells; 2. plants; 3. animals with cold blood; 4. animals with warm blood; 5. Man.

Therefore, the state of the art suggests that the mechanism or the mechanisms which underlie the interactions of the MFs with the biostructures and biosystems (Fig. 4) are still an open question [44]. In this respect, it was suggested that the approach towards the non-equilibrium thermodynamics of the systems under electromagnetic (EM) waves was of primary importance [45].

It still remains to be explained why pulsed EM fields can be more active biologically than continuous ones [46]. This acquires interest in connection with the fact that an alternative basic mechanism of MF bioeffects could be the forced-vibration of all the free ions in proximity of a cell plasma membrane caused by an external AC field. The model proposed by Del Moral and Coworkers [47] explaining the bioelectric activity of single

BIOLOGICAL COMPLEXITY AND MAGNETIC-FIELD SENSITIVITY

unit neurons under DC and ELF MFs, based on the strong anisotropy of diamagnetic susceptibility of membrane phospholipids acting cooperatively (superdiamagnetism), would also seem to deserve special attention.

Remarks on the order of organization of a biological target

The observations concerning the MF-dependence of the volume of a whole cell or its nucleus [4,48] were supported by those regarding the MF-dependence of the electrokinetic properties of nuclei in human buccal epithelial cells [49]. Other studies were devoted to the analysis of the so-called "electromagnetic man" vs. the magnetic resonance tomography [50] and of the effect of MFs on synchronization of mammalian cell permeabilization vs. the MF-dependence of gene delivery [51].

From a methodological point of view, attempts were made to employ the programmed chrono-potentiometry as a tool to study electroporation and resealing of pores in bilayer lipid membranes [52] while an eu-wide initiative, to characterize the biological effects of an electromagnetic field (EMF) on human and mouse cell lines by gene expression, was taken [53].

There is a consensus about the effect of MFs on cell-cycle kinetics. In fact, the changes of FL cell-cycle kinetics, following the addition or deprivation of MFs (Figs. 1 and 2a,b) [4], were consistent with the alteration of the onset of S-phase observed after a 50 Hz MF exposure of normal human fibroblasts [54] and with variation of cell-cycle kinetics and colony forming ability after exposure of budding yeast to 50 Hz magnetic radiation [55]. This was shown to influence, in turn, the change in growth and differentiation of PC6 cells exposed to pulsed EMFs [56].

Although the question about the influence of MFs on the development of programmed cell death remains in many respects open (Fig. 2c), especially in terms of the correlation of ion homeostasis and apoptosis [57], investigations strikingly suggested that the MF causes an inhibition of apoptosis [58]. In fact, Annexin V was shown to counteract apoptosis by inducing calcium influx in human lymphocytic T cells [59] while it was demonstrated that by using the patch clamp technique there is an effect of MF exposure on the calcium channel currents [60]. It was also suggested that membrane dielectric changes may indicate induced apoptosis in HL-60 cells [61]. In any case, there was no question about the influence of the MFs on apoptosis: a transient suppression of X-ray-induced apoptosis by exposure to power frequency MFs in MCF-7 cells was evidenced [62], a change in the rate of DNA repair due to apoptosis mediated by MF exposure was detected [63], an exposure of a neuroblastoma cell line to 50 Hz MFs definitely caused changes in the apoptotic rate [64].

Here follows a list of the harmful AC bioeffects investigated at various levels.

At the morphological level, developmental changes in *Drosophila melanogaster* following exposure to alternating EMFs were observed [65] while effects of permanent MF on wing size parameters of the same insect were found [66].

At the cellular level, there were some effects of extremely low frequency EMFs on mammalian follicle development [67]. ELF EMFs as well as heat shock proved to increase microvesicle motility in astrocytes [68]. In addition, it was observed that both sedimentation and aggregation of erythrocytes were MF-dependent [69].

At the macromolecular level, while stability of the DNA replication reaction to MFs was observed (Fig. 3), electric relaxation processes were shown in lipid-bilayers after exposure to weak magnetic pulses [70]. In the framework of the studies on genotoxicity of radiofrequency signals, the occurrence of DNA damage in cultured human blood cells was seen [71] while there were clear cytogenetic effects of 900 MHz microwaves on human lymphocytes [72]. Also, there were an increase in X-ray-induced gene mutations by exposure to AC MFs in NF-kappa B-inhibited cells and an increase in hypoxanthine-guanine phosphoribosyl transferase gene mutations by exposure to electric fields [73]. ELF-pulsed MFs modulated gene expression in myocardial cells [74] while an effect of UV B radiation and 100 Hz EMFs on DNA synthesis of Jurkat cells was detected [75]. As for protein macromolecules, there was an influence of the high ELF MFs on DNA and RNA polymerases *in vitro* and on a cell-free mismatch repair [76].

At the molecular level, effects of exposure to weak radiofrequency fields on acetylcholine release in hippocampus of freely moving rats were revealed [77]. Effects of 60 Hz MF on the immune system in wistar rats was denounced [78]. Also, at the level of ionic events, factors distorting cytosolic calcium measurements in Jurkat cells during exposure to ELF MFs were revealed [79] while there was a calcium spiking in ROS 17/2.8 cells exposed to ELF EMF [80].

The hypothesis suggesting that the rescue of damaged cells may be the mechanism explaining why MFs, which are not mutagenic *per se*, are often able to increase mutation and tumor frequencies [58], is being considered in a number of laboratories. As a matter of fact, there seems to be a general consensus on MFs which may be indeed correlated with cancer [81]. Effects of a 50 Hz MF exposure were also observed on tumor experimental models [82]. The correlation of the MF action with cancer must also be added to the general concern about the harmful effect of MFs on human health.

Summary

Both old [1-16] and new [83] contributions continue to recognize, on the one hand, that the mechanisms of the MF-bioeffects are not yet understood [84] and, on the other, pave the way towards the assumption of an inverse correlation between the degree of MF-sensitivity and the order of complexity of the biological target (Fig. 4a). Such a hypothesis, by analogy, could be judged in the framework of the known inverse correlation existing between the intensity of the ionizing radiation and the evolutionary state of the species (Fig. 4b) [85]. In other words, although both AC and DC MFs do not cause electron movements inside the atom, their final action might depend on peculiar ontological and phylogenetic features of biodiversity. This idea emerged particularly from the comparison of the interactions between the MFs and the living matter at the molecular, tissue and total-body levels [84]. In fact, at variance with cell-cycle kinetics and cell membrane molecular dynamics, which unequivocally depend upon low-frequency/low-intensity MFs [4,12], the single molecular reactions, as some of those occurring in gene expression, react to these fields to a lesser extent [41-43]. An interest of the differential response to MFs, evolving as a function of the biological complexity, would also appear if one correlated Markov's "biological windows" [86] with the heterogeneous MF-sensitivity established for the various cell-cycle stages [4,54] and, thus, for the whole cell proliferation process.

Abstract

We report about a developed model of single neurone dynamics from where we calculate the effects of low frequency (ELF) magnetic field (MF) upon single neurones and simple neurone networks. Calculations are based on the membrane phospholipids (PP) superdiamagnetism and Ca^{2+} coulomb explosion model and on an extension of the Hodgkin & Huxley (HH) equation under MF. *Integration* of HH equation, under AC MF application, by assuming the membrane as a Kirchoff electrical knot, and within the relaxation-time, τ approximation for the HH $n(t)$, $m(t)$ and $h(t)$ characteristic conductance functions have been performed, obtaining the theoretical time dependence of membrane voltage for hyperpolarization (H) and depolarization (D) processes, so allowing a determination of K^+ , τ_K , and Na^+ , τ_{Na} relaxation times. Calculated frequency spectra of single bioelectric impulse H and D voltages are *lorentzians*, as experimentally observed in single unit neurones of mollusc *Helix aspersa*. On the other hand a model which explains the *frequency window effect* (FWE) in neural tissue is developed, explaining Bawin & Adey's first FWE observation in chicken brain and also our observations of FWE in mollusc *Helix aspersa*, both respectively showing *lorentzian* dependencies for Ca^{2+} efflux, $\phi(f_M)$ and bioelectric frequency $f(f_M)$ with AC MF frequency, f_M i.e a resonance when spontaneous $f_0 = f_M$.

1.- Introduction.-

In the bioelectric activity of neural tissue, either spontaneous or under applied magnetic field (MF) there appear two issues: the generation and structure of the bioelectric impulse and the frequency of it, to which we should add the sinusoidal or alternating (AC) MF induced firing correlation observed between neurones or *AC-MF-synchronization effect* (1). The generation of the impulse, after the refractory time, is one of the main problems of neurone physiology, during which the ATP-Na/K pumps operate. The process by which the impulse starts it is thought to be the result of small sub-threshold voltages sum up to a threshold voltage, V_s where the depolarization (D) process starts, with the entrance of Na^+ ions to the cell, through voltage activated Na^+ -channels. We are not going to treat here this problem, but about the time shape of the impulse once it is formed, dividing it in D and hyperpolarization (H, due the sorting out of K^+ ions through delayed rectifier voltage-operated K^+ -channels). The MF effect on electrogenic pumps, which promote the entrance of 3 K^+ ions against the sorting out of 2 Na^+ ions, making the membrane going to the resting potential, was already considered elsewhere (2), so completing the full scenario. The MF effect on the refractory process is the decrease of impulse D amplitude. All those impulse parts we will see are explained by the *integration* of the Huxley & Hodgkin (HH) equation (3), supplemented by the MF produced Ca^{2+} current, that has been done by assuming the membrane as a Kirchoff *electric knot*, instead of as a parallel conductances network as done so far (4). Regarding to the second issue, the neuron impulse frequency, f strongly changes with the MF intensity, B and in the case of AC MF with the RMS field intensity, $B_{\text{eff}} = B_0/\sqrt{2}$ (B_0 is the AC MF amplitude) and also with the AC MF frequency, f_M . With all those models we have conformed a full picture of the single unit neurone bioelectric behaviour, either for spontaneous regime or under AC MF, this of extremely low frequencies (ELF).

2.- Superdiamagnetism (SD) and Ca^{2+} coulomb explosion (CE) model under AC magnetic fields.-

The explanation of above effects will be based on the membrane phospholipid (PP) *superdiamagnetism* (SD) and Ca^{2+} *coulomb explosion* (CE) model (5, 6). This model has been widely tested in single neurones and simple neurone networks under static and ELF MF respectively, where in the latter the MF also induces a *synchronized* bioelectric activity within those networks (1, 7). The model contemplates three ingredients: i) the anisotropy of the diamagnetic susceptibility tensor components, $\tilde{\chi}$ (< 0) of the long PP “rods”, or difference $\Delta\chi = \chi_{\parallel} - \chi_{\perp}$, between the directions parallel (\parallel) and perpendicular (\perp) to the PP axis; ii) the well proved cluster formation in the membrane liquid crystal of *correlated* PP long axes through their electric quadrupolar moments, \tilde{Q}_i interaction, of pair (i, j) correlation function $C_Q = \langle \tilde{Q}_i \tilde{Q}_j \rangle - \langle \tilde{Q}_i \rangle \langle \tilde{Q}_j \rangle$, by which the PPs cooperatively rotate out from the MF \mathbf{B} axis (SD; PP electric dipolar moment is very weak). $\langle \dots \rangle$ is the ensemble thermal average. The correlation length, ξ usually exceeds a single neurone, *via* the PPs of the interposed glia membranes between neurones, and through the gap junctions (8); iii) when the Ca^{2+} ions attached to their PP bilayer inner and outer binding sites (polar heads) happen to be nearest-neighbours (NN, in number N_m per cluster face, with estimated $N_m \cong 0.007 N_c$, N_c being the PP number per cluster), and the NN PPs suffer opposite (with clearly 1/2 probability) magnetic torques $\boldsymbol{\tau}_m = \pm \mathbf{m} \times \mathbf{B}$, the weak ionic bindings are broken by their mutual coulomb repulsion, of energy ϵ_{coul} . This produces a *simultaneous* detaching (coulomb explosion, CE) of Ca^{2+} pairs (see Fig.1 for a view of the mechanisms involved). Note that the Ca^{2+} water solvating and dielectric mem-

Fig.1.- Schematic view of the mechanisms involved in the SD-CE model. The circular shell represents the membrane neurone phospholipid (PP) bilayer. Two nearest-neighbour Ca^{2+} -charged phospholipids (rods) rotate under their assumed opposite magnetic torques, approaching the Ca^{2+} ions (black circles), attached to the PP negatively charged heads (lozenges). The ions become simultaneously detached from the membrane surfaces when their weak ionic bonds to the heads are broken due to Ca^{2+} - Ca^{2+} coulomb repulsion. Within the cytosol the Ca^{2+} ions diffuse towards the K^{+} -protein channels, which are opened when Ca^{2+} is captured by the “gate” molecule (calmodulin), giving rise to the K^{+} outwards current (hyperpolarization).

brane negative electric images formation reduce the Ca^{2+} effective charge to only $q_{\text{ef}} \cong 0.025 q_{\text{Ca}^{2+}}$, making the ionic bond energy, ϵ_{bind} rather weak. But since ϵ_{bind} is supplemented by the water-PP surface tension energy the bond becomes stable against *normal* to the surface thermal fluctuations (of energy $(1/2)k_B T \cong 8 \text{ meV}$ at r.t.) (5). $\mathbf{m} = \tilde{\chi} \mathbf{H}$ is the field induced diamagnetic PP magnetic moment and it rotates out from \mathbf{B} axis because $|\chi_{\parallel}| > |\chi_{\perp}|$, therefore alternatively approaching the NN Ca^{2+} charged PP heads (Fig.1). The PP magnetic energy is given by $\epsilon_m = -(1/2\mu_0)B^2(\chi_{\perp} + \Delta\chi \cos^2\theta)V$, where θ is the angle formed by the PP axis with \mathbf{B} and $\boldsymbol{\tau}_m = -(\partial\epsilon_m/\partial\theta)\hat{\theta}$, which acts against the opposite coulomb repulsion torque, $\boldsymbol{\tau}_r = -(\partial\epsilon_{\text{coul}}(\theta)/\partial\theta)\hat{\theta}$ (V is the PP volume). Under AC MF the scenario is the detaching from the cluster of gaussian bursts of Ca^{2+} ions for about half a MF cycle, since the magnetic torque is oscillatory, i.e. $\tau_m = (1/2\mu_0)B_0^2 \Delta\chi \sin 2\theta(t) \sin^2 \omega_M t$. The Ca^{2+} detaching occurs when $N_m(\epsilon_{\text{coul}}(\theta) - \epsilon_{\text{bind}}) + N_c \epsilon_m(\theta) \cong 0$, a condition that allows to weak MF to detach about 7 Ca^{2+} per 10^3 PP for large enough N_c (5, 6). Note that the small q_{ef} , the interposed membrane dielectric constant ($\epsilon_r \cong 2.6$) and the final Ca^{2+} - Ca^{2+} approaching distance $d_f \cong 5.3 \text{ nm}$ yield a small energy $\epsilon_{\text{coul}}(\theta_f) = (1/4\pi\epsilon_r\epsilon_0)(q_{\text{ef}}^2/d_f^2)$ at the coulomb explosion angle θ_f . The MF detaching process, which occurs within a spherical apex of 120° around \mathbf{B} , produces a cytosol Ca^{2+} concentration about ten times the normal one and similar to the produced one in the D process (see (6) for greater detail).

The main result from the SD-CE model (5, 6) is the *field intensity dependence* of the neurone bioelectric frequency, $f(B_{\text{eff}}, T)$. This frequency is controlled by chemistry mass action law between Ca^{2+} and membrane binder radical, R^- (sialic acid outside and phosphatidylserine inside), i.e. $[\text{Ca}^{2+}][R^-] = k(T, B_{\text{eff}})[\text{CaR}]$, where k is the kinetics constant. Thus $f \propto [R^-]$ becomes inversely proportional to the number of Ca^{2+} ions detached per cluster, $N_{\text{Ca}^{2+}}^c = N_{\text{nn}} \exp(-\Delta E_c/k_B T)$, where $\Delta E_c(\theta) = -(N_c \epsilon_m + N_{\text{nn}} \epsilon_{\text{coul}})$ is the *dynamic* Peierls's energy barrier to be overcome by the Ca^{2+} ion in order for the PP to steadily rotate. Moreover under AC MF the H process (where the cytosol becomes more negative due the K^+ ions sorting out) is modified by the Ca^{2+} ions (in number of four) binding to the K^+ protein-channel (more specifically to the calmodulin “gate” molecule) and opening it due to the calmodulin electrical unfolding (9). Therefore it should be $f \propto 1/N_{\text{Ca}^{2+}}^c$, to first order. Summing now $N_{\text{Ca}^{2+}}^c$ from all the PP clusters in membrane (s), the final result is that the neurone bioelectric frequency varies with RMS MF as (5, 6)

$$f(B_{\text{eff}}, T) = f(0, T) \exp(-\alpha B_{\text{eff}}^2), \quad [1]$$

where $f(0, T) \equiv f_0$ is the *spontaneous* frequency and the parameter $\alpha = N_c |\chi_{\perp}| V / 2\mu_0 k_B T$, that encompasses the PP cluster physical properties and membrane temperature, T . As mentioned before for ELF AC MF (quasistatic) we have introduced in [1] the RMS B_{eff} , since magnetic energy density stored in the membrane is $B(t)^2 / 2\mu_0$, of time average $B_{\text{eff}}^2 / 2\mu_0$. Eq.[1] has been widely and firmly tested in single neurones of *Helix aspersa* for static (5) and ELF weak MF (1,11) and for T modification, by using standard microelectrode transmembrane voltage real time recording technique. In fact for weak ELF MF the observed f in *Helix* neurones follows a dependence $f(B_{\text{eff}}) \approx f(0)(1 - \alpha B_{\text{eff}}^2)$, which precisely is the obtained one by performing a series expansion of [1] for $\alpha B_{\text{eff}}^2 \ll 1$ (1). Regarding to $f(T)$ dependence, preliminary observations in mapped *Helix* neurones F47 and F2 show that f first decreases with increasing T at fixed B_{eff} , in disagreement with eq.[1] (see Fig.2). The reason is

Fig.2.- Temperature effect for neurone F47 bioelectric activity. Transitions at 30°C and 37°C are observed.

that those neurones belong to the $\approx 26\%$ of studied ones where f increases with increasing B_{eff} (6). The responsible mechanism is that the by MF detached Ca^{2+} ions depolarize the membrane, cytosol becoming more positive, so opening Na^+ and/or Ca^{2+} channels operated by voltage. Also D amplitude V_d decreases, the calculated variation in V_d being $\Delta V_d(B_{\text{eff}}) = -(4\pi/N_c)E_p \exp(+\alpha B_{\text{eff}}^2)$, where E_p is the pump e.m.f., due to opposite to PP protein pump rotation (since $|\chi_{\parallel}| < |\chi_{\perp}|$), where PP partially cover the protein pump (2). Also observed are two transitions in the form of increasing f within a ΔT small interval, at $T_{f1} \approx 30^\circ\text{C}$ and $T_{f2} \approx 37^\circ\text{C}$, corresponding to phase transitions within the membrane liquid crystal. After second transition f decreases with T increase, now in agreement with [1], although temperature behaviour requires deeper investigation, and PP liquid crystal viscosity energy dissipation, $\epsilon_v = -\eta_r(T)\theta(t)$ introduction in SD - CE model (η_r is the viscosity coefficient).

3.- Bioelectric impulse shape and frequency spectrum.-

The D and H main trams of bioelectric impulse (Fig.3) in neurones are controlled by the well known Hodgkin & Huxley equation (3). This equation has been usually referred to an equivalent electric circuit of in

parallel conductances, membrane capacitance, C_m and DC generators, the latter being the equilibrium Nernst Na^+ and K^+ e.m.f., E_{Na} and E_{K} , due to the ions electrochemical gradients. Consideration of this network by meshes does not allow its solution, and we will consider the membrane as a knot where the currents concur

Fig.3.- Neurone V-14 impulse of *Helix*, with D, R and H trans.

Fig.4.- Membrane equivalent Kirchhoff electric knot.

(Fig.4). Therefore HH equation takes the knot law of charge conservation (no charge accumulation in membrane),

$$C_m(dV/dt) + g_{\text{Na}}m(t)^3h(t)(V - E_{\text{Na}}) + g_{\text{K}}n(t)^4(V - E_{\text{K}}) + g_{\text{L}}(V - V_{\text{L}}) - I_{\text{Ca}}(B_{\text{eff}}, t) = 0 \quad , \quad [2]$$

where V is the transmembrane voltage, g_i ($i = \text{Na}, \text{K}, \text{L}$) the channels conductances. m and n are the HH channel excitatory and h inhibitory functions, of microscopic origin not yet well known, although the phenomenologically needed powers four, point out to four independent processes, acting for the opening (m , n) and closing (h) of corresponding channels. Leakage (L) channels and ligand operated ones are probably responsible for the setting of the threshold voltage, V_s but current through them is weak and here neglected. Finally, HH currents have been supplemented by the Ca^{2+} current produced by MF (*HH magnetic* (HHM) equation). We will solve eq.[2] in the *relaxation time*, τ , *approximation* for the HH functions, where e.g.

$$dn/dt = -n(t)/\tau_{\text{K}} \quad [3]$$

where $n(t)$ is assumed to be proportional to the number of K^+ -channels which remain closed at time t . Integration of [3] taking $t = 0$ at the beginning of repolarization (R) plus H process, yields $n(t) = n_0 \exp(-t/\tau_{\text{K}})$. Similarly taking $t = 0$ at the beginning of D process we obtain that function $m(t) = m_0 \exp(-t/\tau_{\text{Na}})$. Otherwise the inhibition function at D process follows the equation $dh/dt = h(t)/\tau_{\text{inh}}$, of integral $h(t) = h_0 \exp(+t/\tau_{\text{inh}})$. We will now obtain the membrane voltage $V(t)$ dependence, partitioning the impulse in the mentioned regimes.

Repolarization and hyperpolarization: these two processes follow one after other and it is well known that in the R+H process only K^+ -channels are open and therefore [2] becomes, $C_m(dV/dt) + g_{\text{K}}n(t)^4(V - E_{\text{K}}) - I_{\text{Ca}}(B_{\text{eff}}, t) = 0$, which integration after substitution of $n(t)$ yields

$$V_{\text{K}}(t) = E_{\text{K}} + (E_{\text{Na}} - E_{\text{K}}) \exp \left[- \left(g_{\text{K}} n_0^4 \tau_{\text{K}} / 4 C_m \right) (1 - e^{-4t/\tau_{\text{K}}}) + \int_0^t dt' I_{\text{Ca}}(B_{\text{eff}}, t') / (V_{\text{K}}(t') - E_{\text{K}}) \right], \quad [4]$$

which is an integral equation with kernel $I_{\text{Ca}}(B_{\text{eff}}, t)$. We will show below (from [1] and [9]) that $I_{\text{Ca}}(B_{\text{eff}}, t) = - (N(0)f(B_{\text{eff}} = 0)q_{\text{Ca}}/\tau_{\text{Ca}}) \exp(-\alpha B_{\text{eff}}^2) \exp(-t/\tau_{\text{Ca}})$, where $N(0)$ is the initial Ca^{2+} ion number in a burst and τ_{Ca} the Ca^{2+} relaxation time (diffusion time in the cytoplasm) (t origin in [4] is taken at $V(t) = E_{\text{Na}}$, origin of R). For comparison with experimental results in single neurones, it is useful to work in frequency domain, ω , so that we will obtain the *frequency spectrum* of spontaneous impulse $V_{\text{K}}(t)$. Fourier transform of [4] $\exp[\dots]$ function is unknown, but for $t < \tau_{\text{K}}$ first exponential can be series expanded, so obtaining

$$V_{\text{K}}(t) \approx E_{\text{K}} + (E_{\text{Na}} - E_{\text{K}}) \left[1 - \left(g_{\text{K}} n_0^4 \tau_{\text{K}} / 4 C_m \right) (1 - e^{-4t/\tau_{\text{K}}}) + \int_0^t dt' I_{\text{Ca}}(B_{\text{eff}}, t') / (V_{\text{K}}(t') - E_{\text{K}}) \right]. \quad [5]$$

The ω spectrum of [5] *spontaneous* $V_K(t)$ ($I_{Ca} = 0$) is obtained by Fourier transforming $V_K(t)$ around a central frequency ω_0^* , characteristic of the impulse, yielding (except for a Dirac $\delta(\omega - \omega_0^*)$ artefact introduced by the exponential series cut-off)

$$V_{Na}(\omega) = A^* / \left[(\omega - \omega_0^*)^2 + (\Delta\omega/2)^2 \right], \quad [6]$$

where $A^* \equiv g_K n_0^4 \tau_K / 4C_m$ and $\Delta\omega/2 = 2\pi/\tau_K$ the HMHW, which provides τ_K . Therefore the impulse spectrum is the familiar *lorentzian* function, taking its maximum value at $\omega = \omega_0^*$. Eqs. [5] and [6] can be easily extended to the real situation of having different types of K^+ -channels (up to seven in *Helix aspersa* (13)), but this extension is not suitable for comparison with the impulse because of the too large number of parameters involved.

Depolarization: this process follows after the refractory time and threshold voltage establishment, and since involved Na^+ channels are operated by voltage, inclusion of Ca^{2+} current sums only a term to $V_{Na}(t)$. But also retarded in time K^+ channels are opened, although being in small number during D tram their current can be neglected. The HHM relevant equation is then $C_m(dV/dt) + g_{Na}m(t)^3h(t)(V - E_{Na}) - I_{Ca}(B_{eff}, t) = 0$, which in presence of MF yields another integral equation. Integration followed by the first exponential expansion as before yields

$$V_{Na}(t) \approx E_{Na} \left[1 - (g_{Na}m_0^3h_0\tau_{eff}/3C_m)\exp(-t/\tau_{eff}) + \int_0^t dt' I_{Ca}(B_{eff}, t') / (V_{Na}(t') - E_{Na}) \right], \quad [7]$$

where the relaxation time is given by $\tau_{eff}^{-1} = \tau_{Na}^{-1} - \tau_{inh}^{-1}/3$, since the inhibition and activation are independent processes. As before the ω -spectrum of spontaneous $V_{Na}(t)$ is lorentzian of $\Delta\omega/2 = 2\pi/\tau_{eff}$, and $A^* \equiv g_{Na}m_0^3h_0\tau_{eff}/3C_m$. Extension to different kinds of Na^+ -channels is not worthwhile because of above mentioned reason.

Comparison with experiments in single neurones: we will compare our HHM model with electrophysiological experiments performed on *Helix aspersa* single unit neurones, a good bench for present studies. Thus in Fig.5 we present the spontaneous ($B_{eff} = 0$) R+H potential time variation for two mapped neurones (14), fitted by the approximate solution [5], the agreement being reasonable, but where we do not reproduced the sigmoidal variation at the ends, due to the series cut-off in [4]. The more “accurate” used “sigmoidal” fit by $(1 - e^{-t/\tau_K})^4$ is also shown, but its basis is purely phenomenological. We took $E_K = -75$ mV, $E_{Na} = +50$ mV (this e.m.f. rectified by the delayed K^+ channels), $g_K = 1.6 \times 10^{-7} m^{-2} \Omega^{-2}$ and $C_m = 4 \times 10^{-2} Fm^{-2}$, and from the fits we obtained the n_0 and τ_K values quoted in Table 1. Clearly we can not identify n_0 with the number of K-protein channels (KP), with a density of ≈ 7 KP/ μm^2 , which for a neurone of 100 μm diameter yields $\approx 2 \times 10^4$ KP. In Fig.6 we show the frequency spectrum of a bioelectric impulse of neurone V19, together with the fitted theoretical one by eq. [6], using the parameter values of Table 1 the agreement being excellent, the same happening for other neurones (not shown). Under applied AC MF we have observed that shape of the impulse becomes *unmodified*, which means that the solution of full integral eq.[4] is not needed. Integral eqs. [4] and [7] can be easily transformed into second order linear differential equations of well known solutions, not given here.

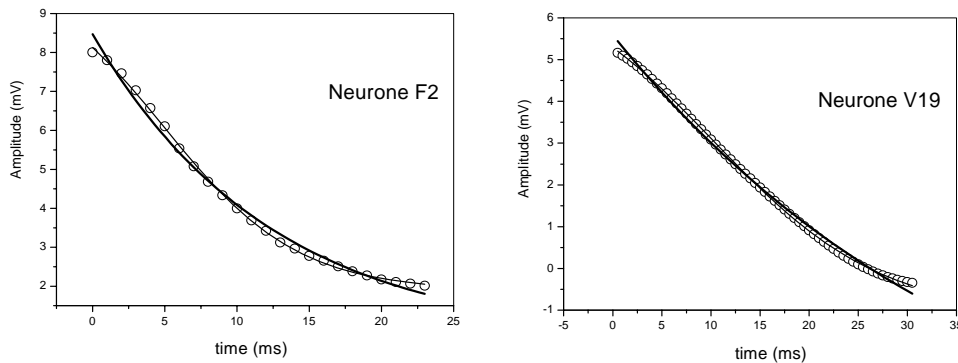

Fig.5.- Experimental (O) and model (thick line) R+H time variations for neurones F2 and V19; sigmoid (thin line).

Fig.6.- Frequency spectrum of R+H tram impulse. Experiment (v) and model fit (full line).

Similarly in Figs. 7 we show the D voltages for the same neurones impulses, fitted by [7], using the above parameter values and $g_{Na} = 1.9 \times 10^{-7} \text{ m}^{-2} \Omega^{-2}$, from the fits obtaining the values of $(m_0^3 h_0)^{1/4}$ and τ_{eff} quoted in Table 1. Values of $(m_0^3 h_0)^{1/4}$ are larger than n_0 ones, and same above consideration apply to them. Also sodium τ_{eff} are larger than τ_K , although in the impulse times $t_s < t_b$ because $V_{Na}(t)$ is interrupted at the smaller (abs.value) E_{Na} than E_K for $V_K(t)$. In Fig.8

is shown the frequency spectrum of $V_{Na}(t)$ for neurone V-19, and the fit by the corresponding lorentzian. D voltage is unmodified by applied AC MF and again solving of R+D equation under MF with I_{Ca} term is not needed.

Fig. 7.- Ibidem Fig.5 for the depolarisation (D) process; lines: thick, model fit; thin, sigmoid.

Overall our HHM model explains well the spontaneous time dependence of the bioelectric impulse and its frequency spectrum. Demonstration that AC MF produced voltage, V_{Ca} is negligible is a mathematical problem

 Table 1.- Initial values of n, m, and h HH functions and K^+ and Na^+ relaxation times.

Neurone	n_0	τ_K (ms)	$(m_0^3 h_0)^{1/4}$	τ_{eff} (ms)
F1	200	33.0	51	92.7
F2	188	49.4	45	149.9
V3	202	45.0	49	109.6
V14	272	12.4	58	57.0
V19	155	156.7	41	222.8

of HHM differential equation resolution as mentioned before. As we will see in Section 3, the main effect of $I_{Ca}(B_{eff}, t)$ is upon the neurone bioelectric frequency.

 Fig.8.- Frequency spectrum (v) for impulse depolarization of neurone V-19. Line is the lorentzian fit, $L(f)$.

4.- Magnetic field frequency dependence of bioelectric activity: frequency window effect.-

The experiments initiated in 1975 by Adey and co. (15) about the effects of ELF MF upon neural tissue are a breakthrough in the understanding of how AC ELF MF interacts with this tissue, apart from its *negligible* Joule heating. They prepared newborn chicken brain slices and embedded them in a physiological HCO_3^- water solution doped with radioactive $^{45}\text{Ca}^{2+}$ as marker. The tissue was then irradiated with a radiofrequency (RF) field of 147 MHz, *amplitude modulated* by an ELF MF (of amplitude 25 - 30 nT) in the interval 0.5 - 35 Hz, observing an increase of $^{45}\text{Ca}^{2+}$ efflux from the tissue. The experiments demonstrated two things: i) the RF (147 MHz) electromagnetic field (EMF) does *not* produce a measurable efflux increase; ii) a calcium efflux increase was observed for the tissue irradiated with the modulated wave, but only within an interval of about 5-25 Hz, so called *frequency window effect* (FWE) (see Fig.9). Recently we have found a FWE in *Helix aspersa* brain, irradiated with microwaves of 9.6 GHz amplitude modulated between 2-25 Hz. Since Ca^{2+} electrochemical gradient, E_{Ca} displaces these ions to the cell interior, the observed efflux was interpreted as Ca^{2+} liberation from the external membrane surface. FWE was afterwards found in many other kinds of cells and experimental conditions (see (6) for a review), in particular for the bioelectric *frequency, f* dependence with the applied ELF MF frequency, f_M in *Helix aspersa* single neurones (16). Our new observation is that the calcium efflux closely follows a *lorentzian* curve, written now in the normalized form,

$$\phi(\omega_M) = \phi(\omega_0) (\Delta\omega/2)^2 / [(\omega_M - \omega_0)^2 + (\Delta\omega/2)^2] , \quad [8]$$

where ω_0 is the frequency at the maximum efflux $\phi(\omega_0)$. Effectively, in Fig.9 the continuous line is the fit by [8] to the experimental calcium efflux (ν points), and where $f_0 = \omega_0/2\pi \cong 14$ Hz and $\Delta f = \Delta\omega/2\pi = 14.8$ Hz.

Fig.9.- The points (ν) are the experimental $^{45}\text{Ca}^{2+}$ efflux increase from chicken brain under application of 147 MHz EMF carrier (intensity 0.8 mW/cm^2), *amplitude modulated* by a MF of frequency, f_M between 0.5-35 Hz and $B_0 \cong 30$ nT (15). The curve is the theoretical lorentzian, fitted according to the model eq.[8] (symbols C (o) and U (λ) respectively correspond to control and unmodulated EM wave experiments).

The quantitative explanation of such a FWE, although profusely mentioned and discussed since then (6), has remained unknown. Although those workers considered that the electric field of the ELF EMF was the responsible for the effect, it seems now clear that it is the MF the responsible one (16). This conclusion also stems from our experiments performed upon single neurones of *Helix aspersa*, submitted to an AC MF, of amplitude $B_0 = 0.1\mu\text{T}$ -1 mT in the range of 0.1 - 80 Hz. We observed for $\approx 56\%$ of the neurones studied a *decrease* in their bioelectric frequency, f with the increase of MF frequency, f_M ($\omega_M = 2\pi f_M$), and that the frequency dependence $\omega(\omega_M)$ follows a *lorentzian* function as well, i.e. there appears a FWE too. Moreover in other experiments at the fixed frequency of 50 Hz and with variable amplitude AC MF, we found a *decrease* of the bioelectric frequency with field, of the form [1] for also about 56% of the neurones studied (1, 11).

The *lorentzian* frequency, f_M dependence either of the calcium efflux to the extra-cellular fluid from chicken neurones, $\phi(\omega_M)$ or the bioelectric frequency dependence $f(f_M)$ in *Helix aspersa* neurones suggest a common origin for the time dependence of the mechanism involved in the Ca^{2+} ions detaching from their binding sites and their final sequestration or capture. This dependence merely is that the amount of Ca^{2+} ions

either freed to the external or to the cytosol sides from the membrane *must* vary in the form

$$N(t) = N(0) \exp(-t/\tau_{Ca}), \quad [9]$$

for an applied ELF MF starting at $t = 0$. This is so *because the Fourier transform of a lorentzian function is an exponentially time decaying function* (i.e. a relaxation mechanism), with relaxation time $\tau_{Ca} = 2/\Delta f$, as we have shown in Section 2. This is our main point in favour of a *resonance* effect for the FWE. The time τ_{Ca} is the one required for performing the process of Ca^{2+} liberation from membrane binders, mainly Ca^{2+} diffusion within the external or cytosol fluids and final Ca^{2+} sequestration either by a protein channel (or by other cytosol structures) or incoming to the radioactivity counter for the externally freed $^{45}Ca^{2+}$ ions. In their diffusion the Ca^{2+} ions traverse a RMS distance $\sqrt{\langle \ell^2 \rangle} \cong \sqrt{D\tau_{Ca}}$, the one for a random walk, where D is the diffusion coefficient of the ion in the fluid (17). Therefore we come up with $N(t)$ obeying a dynamic equation of relaxation $dN/dt = -N/\tau_{Ca}$, as we would expect for a two states system (freed Ca^{2+} and bonded Ca^{2+} to its sites) in thermodynamic equilibrium, with Ca^{2+} decay between the two states. For the Ca^{2+} ions freed to the extra-cellular fluid they will end up fully thermalized and dissolved in it, increasing its concentration ($^{45}Ca^{2+}$ efflux in Adey & Bawin's experiment). For the Ca^{2+} ions liberated to cytosol, they will diffuse and finally will have a certain probability of being captured by a K^+ -protein channel through the calmodulin attractive electric field, E_{pk} (see Fig.1).

We can quantitatively express the above considerations by Fourier transforming the observed lorentzian function $L(\omega_M)$, which represents either the efflux $\phi(\omega_M)$ or the bioelectric frequency $\omega(\omega_M)$ dependencies, around the neurone spontaneous frequency, ω_0 , i.e.

$$N(t) = \int_{-\infty}^{+\infty} L(\omega_M) \omega(B_{eff} = 0) \exp(-\alpha B_{eff}^2) \exp(-i(\omega_M - \omega_0)t) d\omega_M = \quad [10]$$

$$\omega(B_{eff} = 0) \exp(-\alpha B_{eff}^2) \int_{-\infty}^{+\infty} \frac{2(\Delta\omega/2)}{(\omega_M - \omega_0)^2 + (\Delta\omega/2)^2} \exp(-i(\omega_M - \omega_0)t) d\omega_M = \omega(B_{eff} = 0) \exp(-\alpha B_{eff}^2) \exp(-t/\tau_{Ca}).$$

If we now call $N(0) = \omega(B_{eff} = 0) \exp(-\alpha B_{eff}^2)$ to the initially (at $t = 0$) detached Ca^{2+} ion number within a burst, we end up with the Ca^{2+} relaxation [9] (note, in [10] $\omega(B_{eff} = 0)$ is dimensionless). Since τ_{Ca} is related to $\Delta\omega/2$, which is experimentally accessible from the spectra $L(\omega_M)$, we can determine that time from experiment.

The central frequency ω_0 in [10] is assumed to be the spontaneous average bioelectric frequency, so that we obtain a *resonance* or maximum of calcium efflux when $\omega_M = \omega_0$. This resonance mechanism should not be confused with the unspecific stochastic resonance model one. This model is based also on a two-states system, but assuming a critical noise which is modulated by the AC driving agent and reaches a threshold value (18). A difficulty with this model is that the *physical* mechanism involved in the weak AC agent interaction with the system is neither specified nor quantified. Therefore it becomes of questionable application to the distribution of spontaneous bioelectric frequencies, $D(\omega_0)$ (density of frequencies) for the biological system (membrane), also *lorentzian* (setting $\omega_M = 0$ in [8] and [10]). In fact such a distribution has been clearly inferred from our experiments with *Helix* brain neurones, in the form of repetitive narrow bursts of higher frequency (Fig.10), localized in time when f_M is increased, and superposed to the main $f(f_M)$ lorentzian decrease below ω_0 (12).

Fig.10.- Neuron D-5 spontaneous bursts of variable f .

In Fig.9 we show the excellent fit by [8] of the calcium efflux increase vs. f_M , and which means that our SD-CE and Ca^{2+} kinetics model gives a physical and quantitative explanation to the Adey & Bawin's FWE observation (15). According to our assumption chicken cerebral neurones average bioelectric frequency should be $f_0 \cong 14$ impulses/s, to some extent comparable with the mollusc neurones with $f_0 \approx 0.1 - 5$ impulses/s.

Similarly in Fig.11 we present, the bioelectric frequency f vs. f_M variation for *Helix aspersa* brain mapped neurones F1 and V14, under AC MF of $B_0=1$ mT. The fit of $f(f_M)$ by $L(\omega_M)$ is also rather good. Now, as above mentioned, the bioelectric activity is commanded by the AC MF Ca^{2+} ions internally detached towards the cytosol, which join the K^+ -protein channels and open them, giving rise to the bioelectric impulse of K^+ ions sorting out. Therefore this mechanism should be also operative in the chicken brain bioelectric activity, and therefore both experiments reveal the Ca^{2+} simultaneous detaching from both surfaces of the membrane. Besides the determined Ca^{2+} relaxation times, τ_{Ca} are 135 ms (chicken brain) and between 93-365 ms for the studied neurones of *Helix aspersa*. An *ab-initio* calculation of the Ca^{2+} relaxation time, τ_{Ca} is difficult, if we consider the mentioned above kinetics involved. In fact a first principles calculation of the K^+ and Na^+ relaxation times in HH equations is still an open problem, relaxation times left as adjustable parameters as we did in section 2. However for τ_{Ca} if we estimate the mean diffusion length of Ca^{2+} in water, taking $D \approx 10^{-9} \text{ m}^2 \text{ s}^{-1}$, the typical diffusion coefficient for small molecules in water (18), we obtain $\sqrt{\langle \ell^2 \rangle} \approx 30-60 \mu\text{m}$, reasonable values for the studied neurones of average diameter $d \approx 100 \mu\text{m}$ (1, 14).

Fig.11.- Variation of bioelectric frequency, f with MF frequency, f_M . Experiment (λ); lines are lorentzian fits $L(f_M)$, with $f_0=2.5, 2.0$ Hz and $\Delta f/2=9.9, 2.7$ Hz for neurones F1 and V14 respectively.

A final check of the SD-CE model suitability is the obtaining of the clusters PP numbers, N_c in *Helix aspersa* neurones. This can be done by determining the parameter α from the slopes of the above $f(B_0)$ mentioned plots from time synchronized neurone pairs under $f_M = 50$ Hz MF field. (1,7). In Fig.12 are shown such a plots for the pair V13-V23 of the visceral ganglion. Taking $\chi_{\perp} \cong -0.56 \times 10^{-7}$, determined in erythrocyte membranes by combined SQUID magnetometry ($\Delta\chi$) and electrophysiological experiments (5,19), $V \approx 5 \times 10^{-28} \text{ m}^3$, $T \approx 293 \text{ K}$ and α values, obtained from the slopes, we respectively obtain $N_c \approx 4$ and 1×10^{12} PP in a cluster. Considering that the numbers of PP in such a membranes, of average diameters 120 and 103 μm respectively, are $N_{\text{pp}} \approx 2$ and 1.5×10^{11} (1, 7), that numbers throw about $c = N_c/N_{\text{pp}} \approx 42$ and 16 correlated neurones respectively, firing in *synchronized* way with the probe ones, i.e. forming “giant” PP clusters of linear

Fig.12.- Plots of the bioelectric frequency, f vs. B_0^2 ($f_M = 50$ Hz) for *Helix aspersa* neurone pair V23-V13 (14), showing *synchronization* under MF. From line slopes is determined the α parameter.

5.- Conclusions.-

We have integrated, by the first time to our knowledge, the Hodgkin & Huxley (HH) equation for the bioelectric impulse, by considering the membrane as a Kirchoff *electric knot*. Integration has been performed

extension $\approx 300 \mu\text{m}$ (the visceral ganglion has a diameter of about $600 \mu\text{m}$ and *Helix* brain has $\approx 2 \times 10^4$ neurones) (14). Therefore neurones form correlated small networks under ELF weak MF. In the case of the chicken brain we do not dispose of data about the calcium efflux dependence with the modulating MF amplitude B_0 and that calculation is not possible.

under applied AC MF, by partitioning the bioelectric impulse in its depolarization (D) and repolarization (R) plus hyperpolarization (H) regimes. For the spontaneous regimes we have obtained the time variations of the D and R+H voltages, in reasonable agreement with our experiments on single unit neurones of mollusc *Helix aspersa*. The HH characteristic functions $n(t)$ and $m(t)$ (excitatory) and $h(t)$ (inhibitory) have been treated within the relaxation time, τ approximation, from the comparison with the bioelectric impulse obtaining τ_{Na} and τ_K , as well as the initial values of those functions. The calculated frequency spectrum of the impulse is *lorentzian*, in good agreement with experimental one, from the HMHW also determining τ_{Na} and τ_K . The cytosol Ca^{2+} ion current, produced by the SD and CE under AC MF has been calculated, although experimentally the *single* impulse is *not* modified by weak applied MF to *Helix aspersa* neurones. This means that MF produced extra-voltage, $V_{Ca}(t)$ is negligible, its numerical calculation value being deferred for further work.

On the other hand, we have shown that the hallmark Adey & Bawin's *frequency window effect* is a consequence of the phospholipids superdiamagnetism and Ca^{2+} coulomb explosion in the outer surface of the neurones, and that the effect is a *resonance* of *lorentzian* shape, when the MF frequency matches the neurone spontaneous frequency. In *Helix aspersa* single neurones, same mechanism is operating but now due to the Ca^{2+} liberation from the inner membrane surface towards the cytosol, so operating the K^+ channels. In both situations the *lorentzian* spectrum is a consequence of the exponentially decaying relaxation followed by the Ca^{2+} current, freed by the MF to the extra-cellular or cytosol fluids, ions suffering *diffusion* before capture. This diffusion mainly determines the lorentzian spectrum vs. applied MF frequency f_M .

Abstract

In order to give an interpretation at molecular level of the macroscopic effects produced by ELF-EMFs on biological systems, the activities of different enzymes were studied under exposure to electromagnetic fields of 75 Hz. The activities of cytosolic enzymes as well as those of integral or peripheral membrane enzymes were not affected by the field exposure. Only the activities of some lipid-linked enzymes decreased approximately of about 54 % to 61 % with field amplitudes above different thresholds (from 0.66 to 1.35 mTesla). The decrease in enzymatic activity of the field-sensitive enzymes was independent of the time of permanence in the field and was completely reversible. When these enzymes were solubilized with Triton, no effect of the field was obtained on the enzymatic activity, suggesting the crucial role of the membrane, as well as the linkage to it, in determining the conditions for enzyme inactivation.

INTRODUCTION

The interactions between electromagnetic fields of extremely low frequency (ELF-EMFs) and biological systems have been widely investigated [Walleczek, 1995; Kaiser, 1996; Eremenko et al., 1997; Berg, 1999; Ivancsits et al., 2002; Volpe, 2003]. The problem concerning the mechanisms which can determine biological effects is not yet solved [Lawrence and Adey, 1982; Glaser, 1992; Basset, 1993; Barnes, 1996; Lacy-Hulbert et al., 1998; McCann et al., 1998; Weaver, 2002]. The related phenomena are still not clear, but their existence is certain at least in many specific cases. However, a generally accepted interaction model able to explain these phenomena is lacking. A contribution in this direction could be that of an interpretation at molecular level of the macroscopic effects produced by ELF-EMFs. Therefore, our attention was focused on the enzymatic activity which are known to be underlying many biological processes. The hypothesis that ELF-EMFs could affect enzymes activities was tested on a number of soluble enzymes as well as on membrane-associated enzymes. Among cytosolic enzymes hexokinase, pyruvate kinase, glucose 6 phosphate dehydrogenase and adenylate kinase were chosen. The membrane-associated enzymes were: integral membrane proteins such as CaATPase, Na/K,ATPase, succinic dehydrogenase; peripheral membrane proteins such as photoreceptor phosphodiesterase 6 (PDE); lipid-linked proteins such as alkaline phosphatase and acetylcholinesterase. Membrane-bound phosphoglycerate kinase was also assayed.

When exposed to ELF-EMFs of 75 Hz, the activities of soluble enzymes were not affected by the field, whilst those of four enzymes out of eight bound to membrane were lowered dramatically of about 54% to 61%. Moreover, the effects of the applied field on these enzymes vanished when they were mildly solubilized by Triton, suggesting that the membranes could have an important role for mediating the effect of the field on the enzymatic activity. In fact, interesting results involving biological membranes exposed to ELF electromagnetic fields has been already reported [Miller, 1991; Paradisi et al., 1993; Astumian et al., 1995; Baureus-Koch et al., 2003;]. In particular, measurements by fluorescent probes showed changes in lipid molecular dynamics of the cell membrane [Volpe et al., 1998], while electron microscope images of freeze-fractured membranes exposed to the field indicated a significant clustering of the distribution of the intramembrane proteins [Bersani et al., 1997]. The applied field could modify the membrane organization and structure by acting directly on the strong anisotropy of diamagnetic susceptibility of membrane phospholipids [Del Moral et al., 2002]. An interesting result on the effects of ELF-EMFs on carbonic anhydrase entrapped in liposomes seems to exclude the role of the enzyme molecule in favour of the direct action of the field on charged lipids of the membrane [Ramundo-Orlando et al., 2000].

METHODS

Electromagnetic field production. EMFs were produced by an equipment (Biostim Igea, Modena, Italy) mainly used for clinical application and already described [De Mattei et al., 2003; Ravera et al., 2004]. The generator system supplies a square wave with a maximal applied tension of 180 V, a period of 13.3 ms (75 Hz of frequency), a duty cycle of 10%, to a couple of identical coils aligned on a central axis. Each coil, made up of 1000 turns of copper wire of 0.2 mm of diameter, had internal and external diameter of 72.5 mm and 82.5 mm respectively. As the current supplied by the equipment to the coils was not adjustable, different amplitudes of magnetic field were obtained by separating the two coils with different distances. Measurements of the magnetic field B maximal intensity with a gaussmeter showed that it was fairly constant midway between the coils, giving values of about 2.20 ± 0.08 mT when the distance between the coils was 12 cm and about 0.45 ± 0.02 mT at 29.6 cm distance. An error of 0.5 cm in determining the distance between the coils gave an error of 4% in the field measurements. The values of the field near the threshold (see Fig 1) were determined more accurately (sd of 1 %, n=10). Time course of the magnetic field as well as that of the induced electric field were measured as already described [De Mattei et al., 2003; Ravera et al., 2004], at the center of the distance between the two coils where the samples were always placed. Temperature variations of the order of magnitude of experimental error (± 0.1 ° C) were measured with a thermocouple inside the sample in the presence of the applied field.

Enzymatic activities measurements.

Hexokinase activity assay. Hexokinase activity was measured in the presence or in the absence of the field for 1 min after glucose addition (200 mM final concentration) to the reaction mixture containing the purified enzyme. The reaction mixture contained 100 mM Tris-HCl pH 8, 8 mM MgCl₂, 1 mM ATP and 2 µl of Hexokinase (Cat n° 11 426 362 001, Roche), in final volume of 1 ml. Before and after 1 min of incubation 100 µl of the reaction mixture were withdrawn and added to 50 µl of 25% PCA. Each sample was centrifuged shortly at 14,000 rpm and then 100 µl of supernatant was withdrawn and neutralized with 50 µl K₂CO₃. The centrifugation was repeated to remove potassium perchlorate. Aliquots of 100 µl of each neutralized extract were used to assay Glucose-6-phosphate, monitoring NADPH formation by spectrophotometer (340 nm), according to Bergmeyer et al.[1983].

Pyruvate Kinase activity assay. Pyruvate Kinase activity was measured in the presence or in the absence of the field for 1 min after phosphoenol-pyruvate (PEP) addition (0.6 mM final concentration) to the reaction mixture containing the purified enzyme. The reaction mixture contained 100 mM Tris-HCl pH 8, 8 mM MgCl₂, 5 mM ADP and 0.5 µl of Pyruvate Kinase (Cat n° P-1506, Sigma), in final volume of 1 ml. Before and after 1 min of incubation 100 µl of the reaction mixture were withdrawn and added to 50 µl of 25% PCA. Each sample was centrifuged shortly at 14,000 rpm and then 100 µl of supernatant was withdrawn and neutralized with 50 µl K₂CO₃. The centrifugation was repeated to remove potassium perchlorate. Aliquots of 100 µl of each neutralized extract were used to assay Pyruvate, monitoring NAD⁺ formation as already described [Bergmeyer et al., 1983].

Glucose 6 phosphate dehydrogenase (G6PD) activity assay. Glucose 6 phosphate dehydrogenase activity was measured in the presence or in the absence of the field for 1 min after glucose-6-phosphate addition (10 mM final concentration) to the reaction mixture containing the purified enzyme. The reaction mixture contained 100 mM Tris-HCl pH 8, 8 mM MgCl₂, 0.5 mM NADP and 0.25 µl of Glucose-6- phosphate dehydrogenase (Cat n° G-5760, Sigma), in final volume of 1 ml. Before and after 1 min of incubation 100 µl of the reaction mixture were withdrawn and added to 50 µl of pure Aceton. Each sample was centrifuged shortly at 14,000 rpm and then 100 µl of supernatant was withdrawn, added to 900 µl of water and immediately assayed to spectrophotometer (340 nm), to observe the NADPH formation.

All the other enzymatic activities presented in Table 1 were measured following the methods described in the Appendix

Protein concentration

Protein concentrations were determined using the Bradford method [1976].

RESULTS AND DISCUSSION

In order to measure the direct effects of ELF - EMFs on enzymatic activities, the enzymes were studied in purified state when available or in rough extracts from cell-free homogenates. Different length of exposure to the fields lasted from 1 min to 60 min. The effects on enzymatic activities were detectable only during the field exposure. No effects were measured immediately after the withdrawal of the field, suggesting a perfect

EFFECTS OF ELF-EMFs ON ENZYMATIC ACTIVITIES

reversibility of the mechanism. Table 1 shows the activities of different enzymes exposed to ELF - EMFs of 75 Hz frequency and 3.0 mT magnetic field amplitude for 20 min. The activities of the cytosolic enzymes, that is: hexokinase, pyruvate kinase, glucose 6 phosphate dehydrogenase and adenylate kinase were not affected by the field exposure with a statistical significance of $P < 0.001$. Among membrane-associated enzymes instead: alkaline phosphatase, acetylcholinesterase from ghosts or from synaptosomes, phosphoglycerate kinase and membranous adenylate kinase, decreased their activities of about 54%, 60%, 58% 61% and 54% respectively, while either integral membrane enzymes such as CaATPase, Na/K,ATPase and succinic dehydrogenase, or peripheral membrane enzymes such as photoreceptor PDE were insensitive to the applied field.

Table 1. Activities of different enzymes upon 20 min exposure to a field of 75 Hz and 3.0 mT.

Enzyme	Control sample	Sample + field
Hexokinase	47 ± 2 U/mg	47 ± 2 U/mg
Pyruvate Kinase	175 ± 10 U/mg	177 ± 10 U/mg
Glucose 6 phosphate dehydrogenase	75 ± 7 U/mg	73 ± 6 U/mg
Cytosolic adenylate kinase	385 ± 33 U/mg	390 ± 30 U/mg
Alkaline phosphatase	61 ± 2 U/mg	28 ± 1 U/mg
Acetylcholinesterase from ghosts	3.5 ± 0.1 U/mg	1.4 ± 0.1 U/mg
Acetylcholinesterase from synaptosomes	13.7 ± 0.2 U/mg	5.8 ± 0.1 U/mg
Phosphoglycerate kinase	0.465 ± 0.005 U/mg	0.18 ± 0.01 U/mg
membrane Adenylate kinase	177 ± 10 U/mg	81 ± 5 U/mg
CaATPase	21 ± 1 U/mg	20 ± 1 U/mg
Na/K,ATPase	78 ± 5 U/mg	80 ± 5 U/mg
Succinic dehydrogenase	100 ± 5 U/mg	101 ± 5 U/mg
rod outer segment PDE	50 ± 5 U/nmol of Rhodopsin	48 ± 5 U/nmol of Rhodopsin
Alkaline phosphatase in 0.1% Triton	58 ± 2 U/mg	56 ± 2 U/mg
Acetylcholinesterase from ghosts in 0.1% Triton	3.3 ± 0.2 U/mg	3.0 ± 0.2 U/mg
Acetylcholinesterase from synaptosomes in 0.1% Triton	15.1 ± 0.2 U/mg	14.5 ± 0.2 U/mg
Phosphoglycerate kinase in 0.1% Triton	0.43 ± 0.01 U/mg	0.43 ± 0.01 U/mg
membrane Adenylate kinase in 0.1% Triton	175 ± 10 U/mg	180 ± 10 U/mg

Each value represents the mean \pm SD of five measurements. The enzymatic activity is expressed as Units/mg (nmoles of substrate transformed /min/ mg protein). The activity of each enzyme was measured for 1 min before the withdrawal of the field. The solubilization with Triton in itself did not affect the activity of alkaline phosphatase or acetylcholinesterase from blood cells but decreased of about 7.5 % the activity of phosphoglycerate kinase while enhanced of about 10% the activity of acetylcholinesterase from synaptosomes. Such activity differences are usually observed when membrane bound enzymes are solubilized in low concentration of a mild detergent [Helenius and Simons, 1975].

The activities of the field-sensitive enzymes were measured in function of the concentration of their substrates and the resulting Michaelis-Menten kinetics showed a behaviour of a pure noncompetitive inhibition where only V_{\max} was affected by a field exposure. The Lineweaver-Burk plot of the data obtained for acetylcholinesterase from blood cell ghosts showed that K_M remained constant whereas V_{\max} dropped of about 60% when exposed to the field.

The decrease of the enzymatic activities shown in Table 1 of the four enzymes was independent of the time of permanence in the field and appeared constant within the experimental errors under exposure lengths of 1 min to 60 min. In other words, the same decrease in the enzymatic activity was measured independently of the

exposure time, indicating that the effect of the field starts within the first min exposure and remains constant during all the the field permanence. The action of the field seems that to switch the enzyme to a state of a reduced activity which is immediately restored when the enzyme is removed from the field.

The decrease of the enzymatic activities was studied at different amplitudes of the applied field. Fig 1 shows that field amplitude of about 1.35 ± 0.05 mT or 0.80 ± 0.03 mT were the lowest value which produced a supra-threshold response respectively for alkaline phosphatase and acetylcholinesterase from blood cells. At field amplitudes under the thresholds the enzymatic activities were statistically indistinguishable from those of the controls. Similar data were found for the other two field-sensitive enzymes and the corresponding suprathreshold field values were 0.66 ± 0.02 mT or 0.85 ± 0.03 mT for phosphoglycerate kinase or acetylcholinesterase from synaptosomes respectively. The effect of the field on enzymatic activities seems independent of its amplitude above the threshold up to 2.2 mT as well as for the amplitude of 3.0 mT reported in Table 1.

Fig 1. Enzymatic activity of alkaline phosphatase (○) or acetylcholinesterase from ghosts (●) measured during 10 min exposure to 75 Hz magnetic field of different amplitudes. Each value represents the mean \pm SD of five measurements.

When the same experiments were run on the field-sensitive enzymes solubilized by 0.1 % Triton, the results showed that the activities of the solubilized enzymes were not affected by the field (see the last five lines of Table 1) with a statistical significance of $P < 0.001$.

Changing of enzymatic activities due to exposure to ELF-EMFs have already been reported by different workers. However, the differences in the observed effects could be due to the wide variety of the experimental conditions used by the various authors. The choice of field frequency is crucial as the quantistic interaction of the electromagnetic wave with molecules can only operate through frequency windows. However, fields of 60 Hz frequency, close to 75 Hz used in our experiments, caused opposite and small effects on soluble enzymes [Zhang and Berg, 1992; Litovitz et al., 1991; Thumm et al., 1999; Harada et al., 2001]. Many reported changes of enzymatic activities in whole cells and tissues suggest that ELF-EMFs may stimulate a general response to electromagnetic stress. In the case of ornithine decarboxylase for instance, the enzymatic activity was enhanced approximately 1.5 to 4-fold when exposed to ELF-EMFs [Mullins et al., 1999]. However, in this case the experiments were run on entire fibroblasts cells and the exposure to 60 Hz field for 4 hours presumably did not affect the enzyme activity directly. The activity of another soluble enzyme such as enolase was found

EFFECTS OF ELF-EMFs ON ENZYMATIC ACTIVITIES

decreased by 28% in *Escherichia coli* culture exposed for 30 min to a field of 60 Hz [Dutta et al., 1994]., In this case however, the enzymatic activity was assayed in cell extracts, after the withdrawal of the field, and its decrease maybe be due to stress effects induced by the field and not to a direct interaction of the field with the enzyme molecule.

Among integral membrane protein, Na/K,ATPase and cytochrome oxidase were found to increase its enzymatic activity by approximately 30 % and 40% respectively in experimental conditions similar to those described in this paper, under exposure to a pulsed magnetic field of 60 Hz with an amplitude of only 10 μ T [Blank and Soo, 2001]. The frequency window for Na/K,ATPase was very sharp with a maximal change at 60 Hz while at 100 Hz the change in enzymatic activity was only 10%.

The results shown in Table 1 strongly suggest that the field action is mediated by the membrane organization and structure which is crucial in determining the conditions of the enzyme inactivation. However, the effect of the field on the membrane is not sufficient alone to explain the decrease in enzymatic activity: in the case of acetylcholinesterase, it was independent of the source of the membrane, as the activity decrease for the enzyme coming from blood cells (60 % \pm 4%) was not statistically different from that prepared from synaptosomes (58 % \pm 5 %). On the other hand, integral membrane enzymes such as Ca,ATPase and Na/K,ATPase or peripheral membrane enzymes such as PDE were not affected by the field suggesting the importance of the linkage to the membrane. Alkaline phosphatase, acetylcholinesterase from blood cell or from synaptosomes and adenylate kinase from rod disk membranes are lipid-linked membrane enzymes: alkaline phosphatase as well as acetylcholinesterase are known to be anchored to the membrane through a glycosylphosphatidylinositol while adenylate kinase is presumably bound to rod disk membranes through a myristic fatty acid [Notari et al., 2003]. Instead, the kind of attachment to red blood cell membranes of the field-sensitive enzyme phosphoglycerate kinase is not yet known, although a covalent linkage to hydrophobic group such as myristylate has been suggested [Concepcion et al., 2001]. In a recent report [Caseli et al., 2005], the enzymatic activity of alkaline phosphatase incorporated into artificial phospholipid monolayers dropped of about 40 % following a lipid phase transition from liquid expanded to liquid condensed state, when surface pressure increased above 18 mN/m. Fluorescence microscopy revealed that above this pressure, proteins aggregated and formed clusters which would affect the substrate accessibility to the catalytic site and therefore decrease the enzymatic activity. It has also been reported that a pulsed field of 50 Hz is able to induce a decrease in lipid molecular dynamics of cell membranes [Volpe et al., 1998] and significant clustering of the distribution of the membrane proteins [Bersani et al., 1997]. Therefore, we can speculate that the field of 75 Hz would be able to induce a transition of the lipid bilayer to a more liquid ordered phase, as suggested by the sharp threshold behaviour shown in Fig 1, followed by the partition of the lipid-anchored enzymes in clusters with a subsequent activity decrease.

However, the results presented in this paper are important for the interpretation at molecular level of macroscopic effects produced by ELF- EMFs on biological systems. An example could be that of the clinical application of weak EMFs of 75 Hz frequency currently used to accelerate the healing of bone fractures. The molecular mechanisms underlying these empirical observations could originate from alkaline phosphatase inhibition by the pulsed field. As a matter of fact, alkaline phosphatase is commonly used as an osteoblast differentiation marker, although its role in bone formation is still controversial as it could be involved in the process of bone mineralization or in the organic matrix synthesis as well. However, a decrease in its activity was found in concomitance with an increase of the number of human bone cells in culture following dynamic strain [Kaspar et al., 2000].

Another example of field effect which needs a molecular interpretation comes from several studies that indicate that ELF-EMFs affect cell division timing and embryos development of many organisms [Delgado et al., 1982; Dixey and Rein, 1982; Koch et al., 1993]. In particular, the effects of low-intensity electromagnetic fields on the early development of the sea urchin *Paracentrotus lividus*. [Falugi et al., 1987] could be interpreted as due to acetylcholinesterase inhibition. A recent report on exposure of fertilized eggs of the sea urchin *Paracentrotus lividus* to an electromagnetic field of 75 Hz frequency, shows a dramatic loss of synchronization of the first cell cycle, with formation of anomalous embryos linked to irregular separation of chromatides during the mitotic events [Ravera et al., 2006.]. As acetylcholinesterase is thought to regulate the embryonic first developmental events of the sea urchin [Shmukler et al., 1998], its enzymatic activity was assayed in embryo homogenates and found it decreased by 48% when exposed to the same pulsed field. This enzymatic inactivation had a threshold of about 0.75 mTesla, the same field threshold found for the effect on the formation of anomalous embryos. The conclusion is that one of the main causes of the dramatic effects on the early development of the sea urchin by field exposure could be the accumulation of acetylcholine due to acetylcholinesterase inactivation. Moreover, the effects of accumulation of acetylcholine last presumably even after the removal of the field and the consequent reversible restoration of acetylcholinesterase activity. In other words, even though the effects of ELF-EMFs are likely transient, the consequences of the exposure may not be overlooked as they can be irreversible.

On the other hand, some field bioeffect could be positive. It was reported that cholinesterase inhibitors, such as methanesulfonyl fluoride, improve cognitive performance in patients with senile dementia of the Alzheimer type [Moss et al.,1999]. In this case, ELF-EMFs may be of some help for treatment of the disease as a mild tool without pharmacological side effects.

Summary

The hypothesis that ELF EMFs could affect directly enzymes activities was tested on a number of soluble enzymes as well as on membrane-associated enzymes. Among cytosolic enzymes, hexokinase, pyruvate kinase, glucose 6 phosphate dehydrogenase and adenylate kinase were chosen; among integral membrane protein: CaATPase, Na/K,ATPase, succinic dehydrogenase; among peripheral membrane proteins: photoreceptor phosphodiesterase 6 (PDE); among lipid-linked proteins: alkaline phosphatase, acetylcholinesterase and membranous adenylate kinase. Membrane-bound phosphoglycerate kinase was also assayed. When exposed to ELF-EMFs of 75 Hz, the activities of soluble enzymes as well as those of integral or peripheral membrane enzymes were not affected by the field, whilst those of lipid-linked enzymes were lowered dramatically of about 54% to 61%. Moreover, the effects of the applied field on these enzymes vanished when they were mildly solubilized by Triton, suggesting that the membranes, as well as the protein linkage to them, could have an important role in mediating the effect of the field on the enzymatic activity.

Appendix

Erythrocyte membranes (ghost) preparation Erythrocytes, completely free of leucocytes and platelets, were obtained following a method already reported [Pontremoli et al., 1979] with minor modifications, starting from 25 mls human blood treated with 1mg/ml EDTA to avoid coagulation. The sample was centrifuged at 3,500 rpm for 15 min at 4 °C and the pellet containing erythrocytes was collected and resuspended in 130 mM KCl and 20 mM Tris-HCl pH 7.4 (1:1 v/v) and centrifuged thrice at 3,500 rpm for 15 min. In order to obtain the erythrocytes membranes the last pellet was resuspended in hemolysis buffer (1:5 v/v) containing 1 mM EDTA-Na and 10 mM Tris-HCl pH 7.4 and centrifuged at 17,000 rpm for 40 min. The pellet containing erythrocyte membranes was resuspended in few mls of distilled water. Samples were stored at -80°C.

Synaptosomal preparation For synaptosomal preparation, the method published by Rawls [1999] was followed with minor modifications. For each preparation, six dorsal striata were removed from decapitated *Mus musculus* mouse and pooled in ice-cold 100 mM Tris buffer pH 7.4. The striata were transferred to 0.32 M unbuffered sucrose and manually disrupted in a glass homogenizer with a Teflon pestle. The homogenate was centrifuged at 3,000 g for 2 min. The supernatant was centrifuged at 14,000 g for 12 min. The soft pellet was resuspended in 0.32 M sucrose containing 10 mM N-tris(hydroxymethyl)-methyl-2-aminoethanesulfonic acid (TES, pH 7.4), and 4-ml aliquots were loaded onto discontinuous gradients consisting of three layers of Ficoll (Sigma) in sucrose (wt/vol ; 12%, 4 ml ; 9%, 1 ml ; 6%, 4 ml). The gradients were centrifuged at 62,483 g for 35 min. Synaptosomes were harvested from the 9% layer, diluted with 3 volumes of 10 mM TES buffer containing 140 mM NaCl, 5 mM KCl, 5 mM NaHCO₃, 1.2 mM Na₂HPO₄, 1 mM MgCl₂, and 10 mM glucose (pH 7.4), and centrifuged at 14,000 g for 12 min. Synaptosomes were resuspended in 0.5 ml of 10 mM TES buffer (pH 7.4). The preparation was divided into aliquots containing 0.8 mg of protein and centrifuged at 10,000 g for 2 min. Synaptosomes were overlaid with 200 µl of 0.25 M sucrose containing 5 mM TES (pH 7.4) and stored as pellets at -80°C.

Acetylcholinesterase activity Acetylcholinesterase activity was measured by using acetylthiocholine chloride (Sigma) as substrate and monitoring the thiocoline production as already described [Bergmeyer et al., 1983]. Synaptosomal (100 µg of protein) or erythrocyte membranes preparations (200 µg of protein) were added to a reaction mixture containing 0.4 mM acetylthiocholine in 50 mM phosphate buffer pH 7.2. The final volume of 1 ml was kept in the electromagnetic field 75 Hz, 2.5 mT. At different time intervals, aliquots of 100 µl were withdrawn and added to 50 µl of 25% PCA. Control samples were run in the same experimental conditions as above but in the absence of field. Each sample was centrifuged for 3min at 14,000 rpm and then 100 µl of supernatant was withdrawn and neutralized with 50 µl 2 M K₂CO₃. Centrifugation was repeated to remove potassium perchlorate. Aliquots of 100 µl of each neutralized extract were used for thiocoline assay by adding 0.5 mM DTNB in phosphate buffer pH 7.2 (1 ml final volume). Thiocoline reaction with DTNB gave thionitrobenzoate formation ($\epsilon_{405} = 1.33 \text{ mM}^{-1} \text{ cm}^{-1}$) which was monitored spectrophotometrically by following the rise in absorbance.

Phosphoglycerate kinase activity Phosphoglycerate kinase activity was measured in red blood cell ghosts by following a method already described [Bergmeyer et al., 1983] with minor modifications. Ghosts (100 µg) were added to a solution containing 6.5mM glycerate-3-phosphate and 1.2mM ATP in 40 mM Tris HCl pH 8, 120 mM KCl, 10 mM MgCl₂. The final volume of 1 ml was kept in the electromagnetic field of 75 Hz and 2.5 mT.

EFFECTS OF ELF-EMFs ON ENZYMATIC ACTIVITIES

At different time intervals, aliquots of 100 μ l were withdrawn and added to 50 μ l of 25% PCA. Control samples were run in the same experimental conditions as above but in the absence of the field.

Each sample was centrifuged for 3min at 14,000 rpm and then 100 μ l of supernatant was withdrawn and neutralized with 50 μ l 2 M K_2CO_3 . Centrifugation was repeated to remove potassium perchlorate. Aliquots of 100 μ l of each neutralized extract were used for the enzymatic assay by adding 2 μ l of glycinate-3-phosphate dehydrogenase, 0.2 mM NADH, 10 mM $MgCl_2$, 50mM Tris HCl buffer pH 8 (1 ml final volume). The corresponding NADH oxidation was monitored spectrophotometrically by following the decrease in absorbance at 340 nm ($\epsilon_{340} = 6.22 \text{ mM}^{-1} \text{ cm}^{-1}$).

(Na, K)ATPase activity Plasma membrane Ca-ATPase activity was measured in erythrocyte membranes preparation through inorganic phosphate release. The standard reaction mixture contained 30 mM HEPES, pH 7.6, 140 mM KCl, 0.2 mM ouabain, 2 μ g/ml CaATPase activity calmodulin, 2 mM ATP and 0.005 mM free Ca^{2+} (obtained with a Ca^{2+} -EGTA buffer; EGTA was 2mM). 2mM EGTA) in a final volume of 1 ml. Aliquots of erythrocyte membranes preparation (about 70 μ g proteins) were added to the reaction mixture and incubated at room temperature for 20 min in the presence or in the absence of the field of 75 Hz and 2.5 mT. The final volume of 1 ml was kept in the electromagnetic field. At different time intervals, aliquots of 100 μ l were withdrawn and added to 50 μ l of 25% PCA. Each sample was centrifuged for 3min at 14,000 rpm and then 100 μ l of supernatant was withdrawn and neutralized with 50 μ l 2 M K_2CO_3 . Centrifugation was repeated to remove potassium perchlorate. Control samples were run in the same experimental conditions as above but in the absence of field. The released inorganic phosphate was determined colorimetrically as described by Martin and Doty (1949). Blank subtraction was obtained by considering the amount of inorganic phosphate released by parallel samples incubated in the absence of Ca^{2+} and in the presence of 2 mM EGTA.

ATPase activity of erythrocyte membranes was assayed by the pyruvate kinase, lactate dehydrogenase system in which hydrolysis of ATP is coupled to the oxidation of NADH. ATP hydrolysis was measured in the presence or in the absence of the field for 20 min. An aliquot of 0.145 mg/ml erythrocyte membranes preparation was added to the reaction mixture containing 100 mM Tris-HCl pH 8, 2 mM $MgCl_2$, 150 mM NaCl, 50 mM KCl, 1 mM ATP. Aliquots of 100 μ l of the reaction mixture were withdrawn and added to 50 μ l of 25% PCA. Each sample was centrifuged shortly at 14,000 rpm and then 100 μ l of supernatant was withdrawn and neutralized with 50 μ l of 2M K_2CO_3 . The centrifugation was repeated to remove potassium perchlorate. In order to measure the amount of ATP hydrolyzed, 100 μ l aliquots of each neutralized extract were added to 1 ml final vol of reaction mixture containing 0.16 mM NADH, 1.5 mM phosphoenolpyruvate, 8 μ g/ml pyruvate kinase, 8 μ g/ml lactate dehydrogenase, 100 mM Tris-HCl pH 8.0; 5 mM $MgCl_2$. ATP hydrolysis coupled to oxidation of NADH was followed at 340 nm (ϵ_{340} for NADH= $6.22 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$) in spectrophotometers. Ouabain-sensitive (Na^+, K^+)ATPase was determined as the difference between the enzyme activities in the presence and in the absence of 0.1 mM ouabain.

Microsome preparation Bovine liver was chopped and homogenized in 20 mM Tris-HCl pH 7.5 containing 0.25 M sucrose in a Potter apparatus. The homogenate was centrifuged for 10 min at 900 g. The supernatant was collected and centrifuged for 20 min at 20,000 g. The resulting supernatant containing cytosol and microsomes was collected and centrifuged at 100,000 g for 1 hr. The pellet containing microsomes was stored at -80°C .

Alkaline phosphatase activity Alkaline phosphatase activity was measured by using 4-nitrophenylphosphate (Sigma) as substrate and monitoring 4-nitrophenol formation as already described [Bergmeyer et al., 1983]. Microsomes from liver (100 μ g of protein/ml) were added to a reaction mixture containing 4-nitrophenylphosphate (12 mM) 0.1 M glycine, 0.1 mM $ZnCl_2$, 1mM $MgCl_2$ (glycine buffer pH 10.5). The final volume of 1 ml was kept in the electromagnetic field for 20 min. At different time intervals, aliquots of 100 μ l were withdrawn and added to 50 μ l of 25% PCA. Control samples were run in the same experimental conditions as above but in the absence of field. Each sample was centrifuged 3 min at 14,000 rpm and then 100 μ l of supernatant was withdrawn and neutralized with 50 μ l 2 M K_2CO_3 . Centrifugation was repeated to remove potassium perchlorate formed by the reaction between PCA and K_2CO_3 . Aliquots of 100 μ l of each neutralized extract were used for 4-nitrophenol assay by adding 0.1 M glycine buffer pH 10.5 (1 ml final volume) and measuring spectrophotometrically the increase in absorbance at 405 nm ($\epsilon = 1.85 \text{ mmol}^{-1} \times \text{cm}^{-1}$) which is proportional to the nitrophenol produced.

Mitochondria preparation Pieces of rat liver (3 g) were homogenated at ice temperature by Potter-Elvehjem system in 20 ml Buffer containing 0.25M Sucrose, 5 mM HEPES pH 7.2, 1mM EDTA. The liver homogenate was centrifuged for 10 min at 500g, at 4°C . After centrifugation, precipitate was discarded and supernatant was centrifuged again for 20 min at 20,000g. Then the pellet was collected and dissolved in 2 ml of homogenizing Buffer.

Succinic dehydrogenase activity Succinic dehydrogenase activity was assayed by the oxidation of succinic acid to fumaric acid coupled with $K_3Fe(CN)_6$ reduction, following the method of Bonner [1955] with minor modifications. The enzymatic activity was measured in the presence or in the absence of the field of 75 Hz and 2.5 mT for 20 min after addition of mitochondria preparation (0.1 mg of proteins) to 1 ml final volume of the

reaction mixture containing 100 mM Phosphate buffer pH 7.6, 70 mM Na succinate, 2 mM $K_3Fe(CN)_6$. At different time intervals, aliquots of 100 μ l were withdrawn and the reaction was stopped with 0.25 ml Aceton. Then the samples were centrifuged for 3 min at 14,000 rpm, and supernatant was used for the succinic acid oxidation coupled to reduction of $K_3Fe(CN)_6$, which was followed spectrophotometrically at 400 nm (ϵ_{400} for $K_3Fe(CN)_6 = 920 \text{ M}^{-1}\text{cm}^{-1}$).

Rod outer segments and disk membranes preparations In a typical experiment, rod outer segments (ROS) were isolated from 30 bovine retina in dim red light by following the method of Schnetkamp and Daemen [1982] by sucrose gradient centrifugation. Intact ROS were first washed in an isotonic medium containing 40 mM Tris-Maleate pH 7, 120 mM KCl and then centrifuged for 10 min at 1,500 g. Osmotically intact disks were obtained after bursting intact ROS for 3 h in 30 ml of 5% Ficoll (Sigma) in distilled water containing 5 mM DTT and 70 mg/ml leupeptin and then by collecting them in dim red light at the 5% Ficoll surface after centrifuging for 2 h at 25,000 rpm in a Beckman FW-27 rotor [Smith et al., 1985]. The disk membranes were washed in distilled water and centrifuged for 10 min at 1,500 g. The pellet (purified disk membrane preparation) was resuspended in the initial volume of distilled water and stored in the dark at -80°C .

Rod disk phosphodiesterase activity cGMP Phosphodiesterase was assayed as follows. The reaction mixture contained 100 mM MOPS (pH 7.1), 140 mM KCl, 20 mM NaCl, 5 mM $MgCl_2$, 2mM GTP and 5 mM cGMP. The reaction was started by adding 50 μ l of reaction mixture containing 4 μ Ci $[8\text{-}^3\text{H}]$ cGMP (specific activity: 12.7 Ci/mmol) to 50 μ l of purified disk membrane preparation previously bleached in the room light (final concentration: 1 – 2 mg/ml protein). The reaction was run in the presence or absence of ELF-EMF of 75 Hz and 2.5 mT, at room temperature and stopped after 1, 3, 5, 10 and 20 min by adding 5 μ l of 100 mM EDTA to each 20 μ l withdrawn sample and boiling for 2 min. After centrifuging, 10 μ l of the supernatants were analysed by TLC on polyethyleneimine-cellulose developed in one dimension with 1M LiCl. 5'-GMP was added as internal standard. The separated spots corresponding to cGMP and 5'-GMP, visualized under UV light, were cut into scintillation vials, eluted in 0.5 ml of 0.7M $MgCl_2$ /1M TrisHCl pH 7.4 (10/2 v/v), added to 3 ml of Instagel, left overnight and then counted in a LKB liquid scintillation counter.

LIPOSOME: A MODEL FOR PROBING THE INTERACTION OF ELECTROMAGNETIC FIELDS AND BIOSYSTEMS

BOX 65, 00044 FRASCATI -ITALY.

Abstract

Liposomes are very useful model membrane systems: Although they are unable to mimic all the complexity of a cell membrane, they have a well-defined chemical composition, the capacity to arrange themselves in bilayers, selectivity to ionic species and molecules, and many other useful features. Interactions can take place between this model system and electromagnetic fields (EMFs) at different frequencies, from extremely low frequency up to microwave and THz range, so that, a comparative evaluation of the observed effects with different EMF components is allowed. In this context we used cationic Carbonic Anhydrase (CA)-loaded liposomes. The CA was entrapped into these liposomes and the hydrolysis rate of substrate p-nitrophenyl acetate (p-NPA) added in the bulk aqueous phase was adopted as the index of membrane permeability changes. In fact previous kinetic experiments showed a very self-diffusion rate of p-NPA across intact liposome bilayer. Observations reported by our group evidenced that combined 7 Hz sinusoidal ($B_{acpeak} = 50\mu T$) and parallel static ($B_{dc} = 50\mu T$) magnetic fields can induce permeability changes in these liposomes. Further, we reported on the effects of 2.45 GHz microwave exposure (6 mW/g) on the permeability of these cationic liposomes. Finally, we report on the effects of 130 GHz radiation modulated at low frequency of 5, 7 and 10 Hz on the permeability of these cationic liposomes. The enzyme activity, as function of increased diffusion of p-NPA, rises from 23% to 61% over 3 min of 130 GHz radiation modulated at 7 Hz, at incident intensity of 10.5 mW/cm^2 , and a peak electric field of 2.6 kV/cm . The increase of the incident intensity up to 17 mW/cm^2 did not further increase the enzyme activity. This biological model demonstrates an extraordinary sensibility in revealing the influence of EMFs on the lipid bilayer permeability and allowed an interaction mechanism with an ELF magnetic field to be derived.

Introduction

When considering the action of electromagnetic fields (EMFs) on a biological system, the cell membrane is indicated by the most part of studies as the primary site of interaction [1]. Living organisms are made of cells bound by their membranes. They are self-assembly entities; each is organizing a particular combination of phospholipids in the form of a bilayer with other constituents (e.g. proteins) embedded in it. This lipid bilayer existing in all biomembranes is most unique; it serves not merely as a physical barrier but functions as a two-dimensional matrix for reactions. Also the lipid bilayer acts as a conduit for ion transport, as a framework for antigen-antibody binding, as bipolar electrode for redox reactions, and as a reactor for energy conversion (e.g. light to electric to chemical). Further, a modified lipid bilayer performs as a transducer for signal transduction (i.e., sensing), and numerous other functions as well. All these myriad activities require the ultra thin lipid bilayer. In particular, molecular systems that have been suggested to be candidates for direct modulation by

EMFs are the binding of extracellular ligands to the cell-surface receptor sites, and translocation of charged ionic species across the lipid bilayer. Both events lead to the activation of diverse biochemical pathways that transduce signals to internal sites within the cell [2].

In spite of the huge number of papers that have studied the biological effects of EMFs exposure on cell membrane, from an experimental and theoretical point of view [see reviews 3-6], we reckon to have a nearly complete knowledge by now only in the case of thermal effects. These are due to a sharp increase of temperature that can be systemic or localized. Such effects typically correspond to high power radiation. On the other hand, the complexity of the cell membrane we want to study the interaction with leads to hypothesize the possibility of more subtle specific or non-thermal effects. These are due to phenomena that have no dependence on the thermal energy deposited, or for which temperature is merely one of many significant parameters, and can occur even if the external EMF is weak. Research on these specific effects requires an experimental approach enabling to reduce the complexity of the systems involved.

The cell membrane acts as a gateway to the cell, 30% of all proteins within the body are membrane proteins and 60% of drug targets are membrane proteins. Despite its immense complexity, however, the functionality of the membrane is ultimately determined by its mechanical and electrical properties.

In order to reduce the complexity of this biological system, we suggest the use of membrane model so that physical, biochemical, and physiological processes may be isolated and analysed in molecular terms. Amongst these model systems, liposomes are very useful, although they are unable to mimic all the complexity of a cell membrane; they have a well-defined chemical composition, the capacity to arrange themselves in bilayers, selectivity to ionic species and molecules, and many other useful features [7-8]. Liposomes occur naturally and can be prepared artificially from natural or synthetic lipid molecules [9]. They can encapsulate or bind a variety of molecules, such as drug molecules, proteins, nucleotides and even plasmids, into or onto the membrane [10].

For more than 15 years our laboratory has been studying the possibility of the use of liposomes in an effort to clarify the mechanism of how EMFs exposure induce alterations of membrane permeability, focusing the attention mainly on the membrane phospholipidic components [11-14].

In this context cationic CA-loaded liposomes (Fig.1) revealed an extraordinary sensibility toward the EMFs induced-effects.

Fig. 1. Schematic representation of CA-loaded liposomes where the dipolar (e.g. DPPC) and unipolar (e.g. SA) chemical structures in the lipid bilayer are depicted.

They are formed by controlled dialysis of detergent (DIAL) and containing dipalmitoylphosphatidylcholine (DPPC), cholesterol (CHO), and the charged lipid stearylamine (SA). Because entrapping Carbonic Anhydrase (CA) these liposomes could be considered as a bioreactor. To follow any alteration due to EMFs exposure on the permeability of lipid membrane we add in the bulk aqueous phase the substrate *p*-nitrophenyl acetate (*p*-NPA) in great excess to have a steady-state condition limited only by the enzyme activity. Because the *p*-NPA cannot pass freely across the lipid bilayer, or with a very low self-diffusion, any enhancement of its hydrolysis rate can be assumed due to permeability change enabling the *p*-NPA to reach the enzyme into the inside of liposomes. We carry out kinetic measurements by monitoring the appearance of the product of *p*-NPA hydrolysis at its peak of absorbance at 400 nm in a Cary50 spectrophotometer. Typical recorded curves of change of absorbance at 400 nm against time (min) in the sham and exposed samples are shown in Fig. 2. The difference between the *p*-NPA hydrolysis rate in the exposed sample and the sham one is taken as an index of permeability changes due to the exposure. The temperature is always recorded during the entire exposure time.

Fig. 2. Typical recorded curves of the *p*-NPA hydrolysis rate of CA-loaded liposomes during EMFs exposure are shown.

Typically, in these cationic liposomes, a non-zero *p*-NPA hydrolysis rate resulted in the sham samples (Fig. 2). Indeed, due to electrostatic interactions between the enzyme and the positive charge on the lipid membrane, a small fraction of enzyme is located on the surface of liposomes.

In order to normalize the kinetic data obtained with several liposome preparations used throughout our studies, we determine the total activity of CA (100%) released from each liposome preparations after their disruption with detergent (*n*-octyl- β -glucopyranoside). Then, the relative *p*-NPA hydrolysis rates in intact liposomes are expressed as percentage values (%), and calculate for every exposed and sham sample toward 100% of CA.

We speculated that the above experimental system, in contrast to living cells, was well defined and had

only a limited number of parameter, thus allowed to evaluate in a comparative way the biological effects induced by EMFs with different components. This idea was supported by the following findings.

We found that 2.45 GHz microwave radiation (6 mW/g) induced an increase of p-NPA hydrolysis rate from $41\% \pm 7$ to $80\% \pm 11$ in eight different CA-loaded liposome preparations [15]. An S-band exposure chamber, with a coax-waveguide transition bandwidth input 1.7-2.6 GHz, was used. The SAR of the samples was calculated by the experimental curve of the temperature increase inside a water-filled cuvette in absence of thermostatic control. We speculated that the net surface charge in the vesicles might be involved in the response of liposomes to MW field exposure, since the permeability effect could be dependent on electrostatic charge. This idea was supported by the finding that liposomes with higher net surface charge (i.e., DPPC:CHO:SA at 5:3:2 lipid ratio) showed an higher effect than ones with 6:3:1 ratio. We also found that the MW induced-effect on substrate permeation occurred well below (20°C) the phase-transition temperature of liposomes ($\approx 40^{\circ}\text{C}$), in agreement with literature data [16-17]. It should be noted that liposomes exhibit phase transitions which can be triggered by (inter alias) changes in the total or average area of polar heads on the outer monolayer, these transitions has been proposed to induce changes in the membrane permeability which are analogous to microwave-induced permeability changes [18].

We used the same experimental approach in an effort to clarify the mechanism for how extremely low frequency (ELF) electromagnetic fields exposure influences the trans-membrane movement of free ions in cell membranes [19-21]. Such experimental evidences demonstrate a change in free calcium concentration between the extra- and the intracellular medium under the presence of an ELF magnetic field combined with a static magnetic field.

In this context, we investigated whether combined sinusoidal (AC) and static (DC) magnetic fields could affect the permeability of our cationic CA-loaded liposomes under well-controlled field exposure conditions. The magnetic field was generated by a series of perpendicular nested coils. Each set of coils controls the component direct along its axis. In the center of the apparatus a large isofield region (8 cm^3) with a field uniformity of 1% was obtained. The values of the three components of the magnetic field were generated and maintained by the feedback system [22]. We found that 7 Hz sinusoidal ($B_{\text{acpeak}} = 50\mu\text{T}$) and parallel static ($B_{\text{dc}} = 50\mu\text{T}$) magnetic fields exposure induced an increase in the hydrolysis rate of p-NPA in these liposomes [22]. We speculated that the positive charges of SA on the liposome surface might be responsible for the effect. This idea was supported by the findings that the effect was linear with the increase of SA concentration in the lipid mixture and nullified by neutralizing the positive charge of SA, upon going from pH 7.55 to 8.95 in the reaction medium. Moreover, the presence of CA partially located on the external surface of these liposomes would be expected to be a confounding factor in determining the primary target on the membrane for the interaction of the ELF magnetic field. Therefore we studied the influence of ELF magnetic field on the catalytic parameters of the CA. No structural change of the enzyme, as revealed by the K_m values, was found when CA was either free in solution or loaded in liposomes. Further a specific treatment of the liposomes with a protease able to remove the CA partially located on their surface did not indicate any role for the enzyme itself in the effect [23].

Based on these results an interaction model between the magnetic field and the polar structures embedded in the liposomes has been proposed [23]. The proposed model shows the possibility of inducing a precessional motion by applying suitable dynamic magnetic field. As a result, the charged structures (e.g. $-\text{CH}_2\text{CH}_2\text{NH}_3^+$ in SA) on the lipid membrane could move in a way such as to facilitate the passage of external substances right through the membrane [23-24].

The increasing interest in the THz (Tera-Hertz) region of the electromagnetic spectrum, extending from 100 GHz to 10 THz, in biomedical science [25-26], and the scarce knowledge about the biological effects of this THz region on living systems, suggested us to use our experimental approach in the context of the European Project THz-BRIDGE dealing specifically to investigations on diagnostic and potential genotoxic effects induced by THz radiation.

A series of experiments examining the effects of 130 GHz radiations, modulated at low frequency (5, 7 and 10 Hz) on membrane permeability were carried out. The THz radiation were conducted by using a Compact THz Free Electron Laser (FEL) providing coherent radiation at 130 GHz with a 10% relative bandwidth in the form of a "train" of micro pulses of about 50 ps duration each, with 330 ps spacing between adjacent pulses [27]. The overall duration of the train (macro pulse) is 4 μs . Macro pulses can be produced up to a maximum repetition frequency of 10 Hz.

We found that the THz exposure induces an increase of the p-NPA hydrolysis rate on CA-loaded liposomes in a dose-dependent manner. Indeed, by applying an incident power lower than $8\text{ mW}/\text{cm}^2$ the effect was found only for modulation at 7 Hz. By increasing the field power the effect was also found at modulation of 5 and 10 Hz, though always much more less significant than at 7 Hz. We speculated that probably a temperature rise in the exposed sample rather than a modulation at a specific frequency might be responsible for the effect. Therefore, we studied exposure induced membrane changes on liposome at a different phase transition state by exchanging the DPPC with POPC in the lipid mixture. Further, we prepared the latter

liposome in a different manner avoiding the detergent dialysis, thus producing VET liposome populations with a higher diameter *vs.* DIAL ones. POPC liposomes, which are in fluid phase, showed that THz exposure does not induce any increase in liposome permeability, and that the temperature variations recorded in the samples during the exposure were negligible. Based on these results we excluded a thermal-based explanation for the effect.

Electrical double layers form at each side of the cell membrane, in equilibrium, this potential is of the order 100 mV ($E_{\text{bilayer}} \sim 10^7 \text{ Vm}^{-1}$) when the net ion flux (mainly K^+ , Na^+ , Cl^- , Ca^{2+}) through the membrane is zero, and any disturbance of the membrane (e.g. by absorption of electromagnetic radiation in the membrane) can result in a change in the potential difference across the system. In the 130GHz experiments noted above, the peak electric field ($E_{130\text{GHz}}$) was two orders of magnitude lower than naturally developed across bilayers. Despite this comment, the influence of the electric field cannot be excluded for the effect of permeability change on lipid membrane, as the effects appear to be pronounced only within a certain field range (Fig. 3). As living organisms are not adapted to this spectral range of radiation, and the possible resonance characteristics of its action, it may be possible that a relatively small influence causes a pronounced effect.

FIG. 3. Effect of 130 GHz radiation on CA reaction rate of DIAL liposomes. % CA reaction rates as a function of the peak electric field are shown for three different pulse repetition rates: 10 Hz (dark grey), 7 Hz (black) and 5 Hz (light grey), sham (white). Statistical significances are presented as P of unpaired two-tailed t-test at 95% confidence intervals.

Summary

The use of cationic liposomes entrapping an enzyme for the evaluation of permeability changes induced by EMFs on cell membrane has been proposed. This system allows comparative evaluation of the induced effects by exposure at different EMF components. Specifically, membrane components, with typical dipolar (e.g. phospholipids), or unipolar (e.g. cationic amines) structures, may be focused to study and find interpretation keys on the biointeraction phenomenon, under EMFs exposure conditions.

Abstract

The exposure of mouse embryonic stem (ES) cells to extremely low frequency magnetic fields (ELF-MFs) triggered the expression of GATA-4 and Nkx-2.5, acting as cardiac lineage-promoting genes in different animal species, including humans. ELF-MFs also enhanced prodynorphin gene expression, and the synthesis and secretion of dynorphin B, an endorphin playing a major role in cardiogenesis. These effects occurred at the transcriptional level and ultimately ensued into a remarkable increase in the yield of ES-derived cardiomyocytes. These results demonstrate the ability of ELF-MFs to modify the gene program of cardiac differentiation in ES cells without the aid of gene transfer technologies.

INTRODUCTION

Extremely low frequency Magnetic fields (ELF-MFs) have been shown to elicit behavioural changes in intact organisms (1) and affect proliferation and growth factor expression in cultured cells (2,3). Nevertheless, only a few reports suggest that ELF-MFs may affect cell differentiation (4-6).

In the present study, we used murine embryonic stem (ES) cells as an in vitro model of cardiac differentiation and assessed whether ELF-MF (Fig. 1) may be involved in the activation of a gene program of cardiac lineage commitment

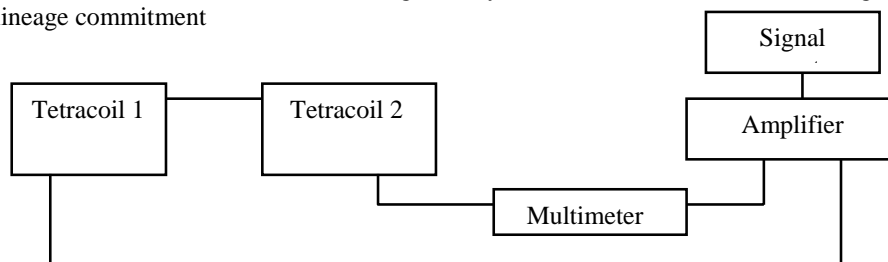

Figure 1

Exposure system and signal characteristics:

- signal generator: Beckman FG3A
- c.c. current amplifier (home made) for low resistive load
- multimeter: Fluke 85III

- two tetracoils, each composed of four coaxial coils, 40 (20+20) turns each, which were double-wrapped to obtain wound (active) or counter-wound (sham) configuration. The inner coils have radii of 10 cm, and the outer of 7 cm. With this configuration a very large region of magnetic field uniformity can be obtained.
- Signal: 50 Hz, sinusoidal, intensity 0.8 mT_{rms}
- The two tetracoils were placed inside the same incubator as shown in the picture.

ELF-MFs were applied to GTR1 ES cells, a derivative of R1 ES cells bearing the puromycin resistance gene driven by the cardiac specific MHC promoter (GTR1 cells were kindly provided by Dr. William L. Stanford, University of Toronto and Centre for Modeling Human Disease, Canada). ES cells were maintained in the undifferentiated state by culturing in KNOCKOUT D-MEM containing 15% FBS, supplemented with 1000 U/ml LIF (Leukemia Inhibitory Factor). To induce cardiac differentiation, cells were plated onto special plates (Costar ultra low attachment clusters), containing KNOCKOUT D-MEM, lacking supplemental LIF. After 2 days, the resulting embryoid bodies (EBs) were plated onto tissue culture dishes. When spontaneous contractile activity was noticed, puromycin (2µg/ml) was added to eliminate non-myocardial cells. After 2 days, puromycin selected cells were transferred to new tissue culture dishes. EBs, collected at several stages after plating, as well as puromycin-selected cells were processed for gene expression analyses. Following LIF removal and throughout puromycin selection, GTR1 cells were also exposed to a sinusoidal ELF-MF (50 Hz, 0.8 mT_{rms}). The analysis of mRNA expression was performed by RT-PCR technique.

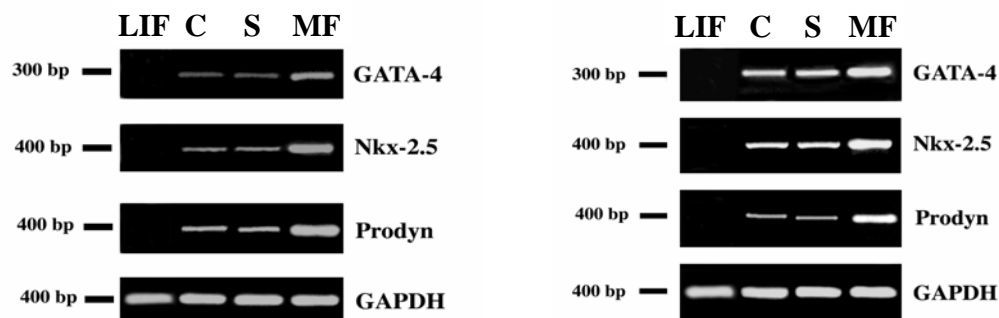

Figure 2

Effect of ELF-MFs on a cardiogenic transcriptional profile in embryoid bodies (left panel) and puromycin-selected cardiomyocytes (right panel). LIF, leukemia inhibitory factor; C, control; S, sham; MF, magnetic field; Prodyn, prodynorphin. GAPDH, (Glyceraldehyde-3-phosphate dehydrogenase) was used as reference.

Exposure to ELF-MFs triggered the expression of GATA-4 and Nkx-2.5 mRNA in both EBs and puromycin-selected cardiomyocytes. Notably, these transcripts encode for a zinc finger-containing transcription factor and a homeodomain, that are both essential for cardiac lineage commitment in different animal species, including humans (7-9). Moreover, ELF-MF increased the expression of the prodynorphin gene, which encodes for the dynorphin family of endorphin peptides, previously shown to act as orchestrators of the transcription of both cardiogenic and cardiospecific genes in mouse ES cells (10,11). Consonant with our previous findings (12), the increase in prodynorphin mRNA was associated with an increase in the expression of dynorphin B, a bioactive end-product of the gene (not shown).

The attainment of a cardiac fate was inferred by the observation that ELF-MFs also elicited the expression of cardiac specific genes, including myosin light chain 2-V and alpha-myosin heavy chain, as shown in Fig. 3.

On the whole, the over-expression of both cardiogenic and cardiac-specific genes induced by ELF-MFs ensued in a remarkable increase in the yield of ES-derived spontaneously beating cardiomyocytes.

Figure 3

Effect of MF on the Expression of Cardiac Specific Genes.

Left panel, ELF-MF was applied from the time of LIF removal and EBs were collected after 3 days.

Right panel, ELF-MF was applied from the time of LIF removal throughout puromycin selection. Four days after puromycin addition, ES-derived cardiomyocytes were processed for gene expression analyses. MHC, alpha-myosin heavy chain; MLC, myosin light chain-2V; C, control cells; S, Sham; MF, magnetic field.

To assess whether commitment to other cell lineages were recruited by ELF-MF, we investigated the expression of neurogenin-1, a gene involved in neuronal specification, and myoD, a transcript associated with skeletal myogenesis. While myoD was not affected by cell exposure, neurogenin-1 mRNA was only slightly increased in EBs (Fig. 4).

Figure 4

Effect of ELF-MF on the expression of genes promoting non-myocardial lineages.

Left Panel, ELF-MF was applied from the time of LIF removal and EBs were collected after 3 days.

Right panel, ELF-MF was applied from the time of LIF removal throughout puromycin selection. Four days after puromycin addition, ES-derived cardiomyocytes were processed for gene expression analyses. Ngn, neurogenin1, determination gene; C, control; S, Sham; MF, magnetic field.

Summary

The development of a model of *in vitro* cardiogenesis based on “gene trapping” selection of cardiomyocytes from pluripotent GTR1 cells provided a homogeneous and reproducible approach to assess the effect of MF on developmental decisions in ES cells.

In this model of cardiogenesis, MF elicited the expression of a gene program of cardiogenesis, along with the induction of cardiac-specific transcripts.

MF failed to activate skeletal myogenesis but slightly enhanced the expression of a vertebrate neural determination gene.

These results demonstrating the potential use of magnetic fields for modifying the gene program of cardiac differentiation in ES cells without the aid of gene transfer technologies may pave the way for novel approaches in tissue engineering and cell therapy. Within this context we are now planning to investigate whether ELF-MF with different physical characteristics (frequency, amplitude and wave shape) may influence cell lineage commitment even in human mesenchymal stem cells.

Abstract:

The ever-increasing use of cellular phones and increasing number of associated base stations are becoming a widespread source of non-ionizing electromagnetic radiation.

In this study, we submit an animal study in a confined, well-controlled environment, with an intention to investigate effects of GSM Base Transceiver Station (BTS) EM radiation on oxidative stress and generation of free radical. During this study a group of young adult male Wistar albino rats was exposed to EM fields inside a test chamber, while another group was sham-exposed under the same conditions. Malondialdehyde (MDA) levels were assessed as a marker of lipid peroxidation and the activities of GSH and SOD were determined in order to evaluate antioxidant status in the blood samples of exposed rats.

MDA level was increased significantly ($p < 0.0001$) for the experiment group when compared to the sham-exposed group. SOD activity was also increased for the experiment group, although less significantly ($p = 0.019$), when compared to the sham-exposed group. GSH concentration decreased significantly ($p < 0.0001$) for the experiment group when compared to the sham exposed group.

Our results indicate that exposure to EM fields at BTS frequencies may modulate the oxidative stress of free radicals by enhancing lipid peroxidation and reducing the concentration of GSH.

Keywords: Electromagnetic field, base transceiver station, antioxidants, oxidative stress, GTEM.

1. INTRODUCTION

The fast growing second generation mobile phone system, Global System for Mobile Communications (GSM), has become the world's largest mobile telecommunications system, with its one billion subscribers in over 200 countries [1]. Electromagnetic (EM) radiation produced by mobile phone and their base station antennas are in the 890 – 960 MHz frequency range for the GSM900 system. While mobile phones emit low power (2 Watts or less) EM fields in the 890 – 915 MHz range, the base station emissions are much higher in power and in the 935 – 960 MHz range. Since mobile phones are kept and used near the body, in particular near the head, emissions should be analyzed in the near field. On the other hand, base station radiation must be modeled with far field considerations. Another concern on base stations is the continuous emission of EM radiation. Therefore, residents who live close to base stations may have a bigger health concern than the casual users of the mobile phones.

There are a number of governmental and independent organizations working on the regulation of the EM radiation from mobile phones and their base stations. As a result useful guidelines and directives have been placed in act [2, 3]. These guidelines, however, focus on the SAR values, which addresses the energy deposition in the body in terms of heat. In May 2000, in IEGMP *Mobile Phones and Health* report [4], concerns were reaffirmed in the following statement, as: "...There is now scientific evidence, however, which suggests that there may be biological effects occurring at exposures below these guidelines..."

A relatively recent comprehensive survey on mobile phone health effects, published by NRPB (UK) [5], summarizes 26 reports from several countries. The survey concludes that although the possibility of low level EM field exposure causing adverse health effects remain "unproven", additional well targeted, high quality research will be valuable to explore the remaining uncertainties further.

One of the areas of interest by scientists in recent years is the EM radiation induced oxidative stress in biological systems. The issue was first studied for the extremely low frequency (ELF) range, particularly for the power-line frequency the magnetic fields [6, 7]. Some recent studies also address effects in radio frequency (RF) range, especially for the mobile telecommunications emissions [8, 9, 10, 11].

Free radical is a molecule or ion that has an unpaired electron in its outer orbit. Radical particles are unstable and are very reactive. Most common free radicals are produced from oxygen metabolism and are, thus, called as reactive oxygen species (ROS). Free radicals start chain reactions as the unpaired electron is transferred from one molecule to another. One known consequence of this kind of a chain reaction is the lipid peroxidation, where reactive radicals, such as NO_2^- , OH^- or CCl_3O_2^- , abstract an atom of hydrogen from poly-unsaturated fatty acid (PUFA) side chains in membranes or lipoproteins. This leaves an unpaired electron on carbon. The carbon radical reacts with oxygen and the resulting peroxy radical attacks adjacent fatty acid side chains to generate new carbon radicals and so the chain reaction continues. The attack of one reactive free radical can oxidize multiple fatty acid side chains to lipid peroxides, damaging membrane proteins. This makes the membrane leaky and eventually causes complete membrane breakdown [12]. MDA is one of the end products of lipid peroxidation which is mostly used as an oxidative stress marker.

There are experimental evidences that oxidative stress and consequent free radical production are important causative factors in the pathology of several degenerative disorders; such as neurodegenerative diseases, carcinogenesis, atherosclerosis, hypertension and diabetic mellitus [13,14,15,16]. Oxidative stress refers to the cytotoxic consequences of oxygen radicals, such as superoxide anion (O_2^-), hydroxyl radical (OH^\cdot) and hydrogen peroxide (H_2O_2), which are generated as byproducts of cellular aerobic metabolism. Oxygen radicals can attack DNA, proteins and lipid membranes, thus disturbing their physical function.

Fortunately, there are enzymatic systems to counterbalance the production of ROS. Superoxide dismutase (SOD), catalase (CAT) and glutathione peroxidase (GSH-Px) are enzymes responsible for

BASE STATION EFFECTS ON OXIDATIVE STRESS IN RATS

degradation of $O_2^{\cdot -}$. While SOD converts $O_2^{\cdot -}$ to H_2O_2 , GSH-Px converts H_2O_2 to water and oxygen. GSH-Px uses H_2O_2 to oxidize reduced glutathione (GSH). Decreased activity of GSH-Px leads to accumulation of H_2O_2 , which in the presence of iron and copper promotes the Fenton reaction to yield OH^{\cdot} . Hydroxyl radical is the most reactive form of oxygen radicals that can initiate a chain reaction to generate numerous toxic reactants. GSH-Px also participates in detoxification of lipid peroxyl radicals [17, 18].

In this article, we submit an animal study in a confined, well-controlled environment, with an intention to investigate effects of GSM Base Transceiver Station (BTS) EM radiation on oxidative stress and generation of free radical. During this study a group of young adult male Wistar albino rats was exposed to EM fields inside a test chamber, called Gigahertz Transverse Electromagnetic (GTEM) Cell, while another group was sham-exposed under the same conditions. Malondialdehyde (MDA) levels were assessed as a marker of lipid peroxidation and the activities of GSH and SOD were determined in order to evaluate antioxidant status in the blood samples of exposed rats.

2. METHODS

2.1 Exposure Environment

The test setup is a general purpose EM shielded chamber that is suitable to house laboratory animals. In this exposure environment electromagnetic radiation of specific energy, frequency and waveform can be applied. The main element of the setup (Figure 1) is a GTEM Cell [GTEM 1750, MEB, Germany], installed in Electromagnetic Compatibility (EMC) Laboratory of TUBITAK-UEKAE.

GTEM Cell is a radiated field generation and measurement device that has a single input/output port for EM immunity and emission test purposes. GTEM Cell, in essence, is a transmission line terminated with $50\ \Omega$ load. The asymmetrical inner conductor (called “septum”) is designed to match the impedance of a tapered, rectangular wave guide cross section. The outer surface of the GTEM Cell is made of metal sheets with an attenuation of around 60 dB at high frequency EM fields. Note that honeycomb waveguides are installed at the bottom of the GTEM Cell for ventilation purposes. Electric field level is directly proportional to the amplitude of the voltage applied to the input port and inversely proportional with the septum height. In order to obtain increased field level with constant input power, cages that contain the test subjects are designed and placed closer to the input port of the GTEM Cell for the purpose of biological effect studies as illustrated in Figure 2

Signal generators, are used to feed the input port of the GTEM cell in order to imitate the electromagnetic fields emitted from base transceiver stations. A properly selected signal generator [SMY01, Rohde&Schwarz, Germany] generates the 945 MHz carrier wave which is then pulse modulated at 217 Hz [using Stanford Research Systems DG535 Digital Delay/Pulse Generator, USA] in accordance with GSM specifications. Output of the signal generator is then connected to a 100W power amplifier [757LCB-CE, Kalmus, USA]. Power feed to the GTEM cell input is provided through a directional coupler. One port of the directional coupler is connected to a power meter [Rohde&Schwarz NRVS with thermal probe NRV-Z51] through which applied power level is monitored (Figure 1).

The rats are enclosed inside two “*metabolic cages*” which are placed adjacent to each other. These cages are designed so as to feed and water the rats and collect urine samples through its structure. The cages are composed of transparent Plexiglas material. It is thus assumed that the cages have minimal effect on the applied electric field. The rats are free to move inside a volume of 24 cm (W) x 34 cm (L) x 12.5 cm (H). The applied electric field is perpendicular to the plane on which the rats move; therefore each animal is exposed to the field without any obstruction caused by its “neighbors”.

2.2 SAR Calculation

It is necessary to make the dosimetric evaluation of an electromagnetic field exposure experiment in order to deduce meaningful results and compare various biological effects produced with different test setups. Dosimetric evaluation is performed, in general, in terms of Specific Absorption Rate, known as “SAR” in short. Since exposure from Base Transceiver Stations (BTS) is generally in the far field, whole-body average SAR is taken into consideration in this experiment. Whole-body average SAR is defined as the total energy, transferred to the body per unit time, divided by the total mass.

The Finite-Difference Time-Domain (FDTD) method implemented in a MATLAB program was used to compute the expected SAR values on the subjects in a simulation environment.

In order to validate the numerical model and MATLAB implementation of the FDTD technique, electric field levels were measured at 10 selected positions on an XY plane located at the middle of the Z axis and compared with those that were obtained by the FDTD technique. These points were selected such that they represent the position of the rats in metabolic cages during actual EM exposure. The simulation software was executed for three times for different input power levels. Electric field levels were also measured by an electric field meter [Acterna EMR-300 with Type 8 E-field probe, Germany], again at those specified input power levels. We found out that FDTD model closely simulates the actual exposure environment (less than 7% difference in the average electric field levels). Thus, the model is a good approximation of the real life measurements. Electric field measurement results also indicated that a fairly uniform electric field was applied to the test subjects in the exposure environment.

The test subject was, on the other hand, modeled roughly with an effort to maintain some details of its geometry. The rat, as a whole, was modeled using electrical properties at 945 MHz, calculated for average muscle tissue, corresponding to: $\epsilon = 55.853462$ and $\sigma = 0.985515$. Rat muscle tissue density was taken as, $\rho = 1040 \text{ mg/cm}^3$. For the sake of simplicity, rat cages were not included in the model since they are transparent to electromagnetic radiation. Normalized SAR value for this exposure environment was found to be 0.90 mW/kg per input W. Thus, when this exposure setup is used for assessment of biological effects, we can compute the SAR values through the FDTD model easily once the GTEM input power level is given.

2.3 Electromagnetic Exposure

Calculations above show that in this test environment SAR values we can induce are well below the safety standards [3]. A set of exposure experiments was performed in two phases to investigate the biological effects of the electromagnetic fields at GSM BTS frequency. The first phase was the EM field exposure experiment and the second was the sham exposure (see Table 1). In each phase, the following procedure was applied:

The animals were obtained from the Experiment Animals Center of Istanbul University Cerrahpasa Medical School. For each of the two phases a set of 9 healthy, young adult male Wistar albino rats were used. The rats were cared for in accordance with the Guide for the Care and Use of Laboratory Animals [20]. The rats have been fed with standard pellet food and watered by tap water ad libitum. The rats have been weighted before, after and at each day of the experiment. Average weights of both groups before and after the experiment and their average food and water consumption are given in Table 2.

The subjects were placed inside two metabolic cages, 5 rats in one cage and 4 rats in the other. The cages were placed in the test volume inside the GTEM cell as shown in Figure 2. Radiofrequency EM field (3.67 W/m^2 power density) was applied onto the exposure group for the first phase, while there was no EM field exposure onto the sham group, in the second phase. We could only apply a low power level, which corresponds to a SAR value of 11.3 mW/kg, because of the time averaging of the applied peak power level in accordance with the GSM modulation of the carrier wave. The cages containing the rats were kept inside the GTEM Cell for 7 hours for a period of 8 days for each group.

2.4. Metabolite Gathering and Analysis

At the end of each phase, the animals were anesthetized. After exploration of the thorax, intracardiac blood was quickly obtained. The tubes containing the processed blood samples were stored at -24°C until they were analyzed at the Cerrahpasa Medical School Biochemistry Laboratory. These samples were processed for measuring MDA, GSH and SOD levels. The materials collected were analyzed using a spectrophotometer [JASCO V-530 UV/VIS] according to standard laboratory procedures [21,22].

MDA level was determined in plasma using the principle of spectrophotometric determination of absorbance at 535 nm of colored complex which is formed by condensation of two molecules of thiobarbituric acid and one molecule of the material that it reacts with. For this purpose, 1 ml of a stock solution, which was prepared from trichloroacetic acid, thiobarbituric acid and hydrochloric acid, was added to 0.5 ml of plasma. After pipetting, tubes were closed and put inside a boiling water bath for 20 minutes. After cooling down, they were centrifuged at 2000 cycles/min for 10 minutes. Absorbance of the supernatant solution was read against the blind solution. MDA level is given in millimoles per liter (mM/L).

BASE STATION EFFECTS ON OXIDATIVE STRESS IN RATS

GSH concentration was determined in total blood by color reading at 412 nm of the solution that is formed by the reaction of free sulfhydryl compounds in the whole blood with 5,5'-Dithiobis (2-nitrobenzoic acid) (DTNB). Note that DTNB is a disulfide chromogen that is readily reduced by sulfhydryl compounds to an intensely yellow compound and the absorbance of the reduced compound is directly proportional to the GSH concentration. Cuverts were prepared for GSH calibrator, erythrocyte and precipitating agent. After incubating at room temperature for 5 minutes, the solutions were centrifuged at 3000 cycles/min for 10 minutes. Upper phase was extracted and phosphate buffer, DTNB and distilled water were added. The color reading was performed at 412 nm against the blind solution in 4 minutes. Using glutathione standard curve did the calculation. GSH concentration was expressed in milligrams per gram hemoglobin (mg / g Hb).

The method of determination of SOD activity was based on the reduction of nitroblue tetrazolium by superoxide anions that were formed by xanthine/xanthine-oxidase system and then inhibition of superoxide anions by SOD. Reaction mixture used to determine the SOD activity in erythrocytes was prepared using xanthine, EDTA, nitroblue tetrazolium, Na_2CO_3 and bovin serum albumin at specified concentrations inside a 200 ml flask. Reaction mixture was set to a pH level of 10.2. Supernatant solution was prepared using chloroform letanal, erythrocyte and distilled water. This solution was centrifuged at 15000 cycles/min for 10 minutes. Test and blind solutions of 1.07 ml were incubated at 25 °C for 20 minutes. After adding 0.05 ml of CuCl_2 (8 mM/l) reaction was stopped. Note that the 50 % inhibition with respect to the blind inside the reaction tube corresponds to 1 unit of SOD activity. The units of SOD activity was determined by simple linear ratio. But it had to be further determined with respect to the hemoglobin concentration inside the solution, so the resultant SOD activity was formulated in terms of units per gram hemoglobin (or U / g Hb).

Hemoglobin concentration for GSH and SOD analysis was determined using Drabkin's reagent. 3 mL reagent was mixed with 1:20 hemolysate and kept in dark for 10 minutes. Absorbance at 540 nm was read against a blank of Drabkin's solution and hemolysate hemoglobin concentration was determined from a calibration curve.

Data was presented as means standard deviation. SPSS software package (SPSS for Windows release 11.50) was used for statistical analysis. The analysis results were evaluated based on Mann-Whitney U test statistics and a $p < 0.05$ was considered significant.

3. RESULTS

Lipid peroxidation (MDA – malondialdehyde), GSH (reduced glutathione) and SOD (superoxide dismutase) analysis results are given in Figure 3, Figure 4 and Figure 5, respectively. Levels of all the three parameters of interest have been changed significantly under EM radiation effect. MDA level was increased significantly ($p < 0.0001$) for the experiment group (10.20 ± 0.78 mM/L) when compared to the sham-exposed group (6.77 ± 0.60 mM/L). SOD activity was also increased for the experiment group (2.53 ± 0.87 Units / mg Hb), although less significantly ($p = 0.019$), when compared to the sham-exposed group (1.79 ± 0.72 Units / mg Hb). GSH concentration, on the other hand, decreased significantly ($p < 0.0001$) for the experiment group (7.84 ± 1.15 mg / g Hb) when compared to the sham exposed group (19.19 ± 1.64 mg / g Hb).

4. DISCUSSION AND CONCLUSION

A two-phase experiment was designed in order to investigate the effects of EM fields at GSM BTS transmitter frequencies. In the first phase, EM field at 945 MHz of 3.67 W/m^2 power density, which is calculated to produce a SAR value of 11.3 mW/kg, was applied on a group of 9 rats inside a GTEM Cell. In the second phase, the same number of rats was sham exposed under the same conditions. The duration was 7 hours/day for a period of 8 days, in each phase.

Biochemical analysis of blood samples indicate that the GSM BTS EM radiation exposed rats have higher concentration levels of MDA (malondialdehyde) and lower GSH (glutathione) concentrations when compared to the sham exposed group. This outcome is in agreement with the results of some previous studies. Dasdag et al. [9] studied the effects of mobile phone EM radiation on rat brain tissues, where rats are exposed to EM fields for 20 min/day for 30 days ($\text{SAR} = 0.52 \text{ W/kg}$). The MDA levels in rat brain tissues increased significantly after exposure. In another study by Ozguner et al. [11], renal impairment in rats was investigated under mobile phone radiation ($\text{SAR} = 0.016 \text{ W/kg}$). Rats were exposed 30 min/days for 90 days and the result was increase of renal tissue MDA, NO (nitric oxide) and urinary NAG (N-acetyl- β -D-glucosaminidase) levels

and significant decrease of tissue SOD, CAT (catalase) and GSH-Px (glutathione peroxidase) levels. Ilhan et al. [10] studied mobile phone induced oxidative stress in rat brain. Rats were exposed to mobile phone emissions (SAR=0.25 W/kg) for 1 hour/day for 7 days. MDA and NO levels were increased whereas GSH-Px and SOD activities were decreased significantly in rat brain tissue. Additionally, XO and ADA levels were also increased. Moreover, Moustapha et al. [24] have studied acute mobile phone exposure effects on human volunteers and found out that MDA level in plasma was increased and GSH-Px and SOD activities were decreased in human erythrocytes after 1h, 2h and 4h of exposure. No significant change was observed for CAT activity in this study.

However, some other studies in literature have concluded in no relation between EM field exposure and free radical activity. Irmak et al. [24] have shown that EM radiation from mobile phones applied 30 min/days for 7 days on rabbits had no significant effect on rabbit brain, suggesting that oxygen free radicals were not generated. But, they have observed a significant increase in serum SOD activity in the exposed group. In addition, Zmyslony et al. [8] have exposed rat lymphocytes in vitro to 930 MHz continuous wave (CW) radiation inside a GTEM Cell (SAR=1.5 W/kg). Five min and 15 min acute exposure resulted in no change in reactive oxygen species production in living cells. However, change was observed when lymphocytes were treated with FeCl₂ as a stimulating agent.

Some research studies relates oxidative stress to certain diseases. In a Parkinson's disease model SOD, CAT and GSH-Px activities were increased in striatum and ventral midbrain of mice [25]. In another Parkinson's disease model Thiffault et al. [26] showed an increase in SOD activity with no increase in GSH-Px activity in mice brain. Neuronal GSH deficiency and age dependent neurodegeneration were found to be related with the down regulation of excitatory amino acid transporters in mice [27].

According to our results, MDA level and SOD activity were increased, whereas GSH concentration was decreased in EM radiation exposed rats when compared to sham-exposed group. We think that decreased GSH concentration may be due to the higher consumption of GSH for scavenging the higher production of free radicals. The lower GSH concentration may have some relation to the increased SOD activity. Note that the endogenous GSH has a protective function in scavenging radicals and in molecular repair. However, such scavenging can set up a superoxide-dependent chain production of H₂O₂ and oxidized glutathione, which would oxidatively stress the cell. Therefore, the increased SOD activity may be a response to suppress the higher chain oxidation of GSH, or a response to balance the decreased GSH concentration.

Thus, the up regulated SOD activity converts O₂^{•-} to H₂O₂ and down regulated GSH concentration leads to the insufficient detoxification and accumulation of H₂O₂ in the system. H₂O₂ is known to be converted to hydroxyl radical in the presence of iron rapidly, which is the most damaging form of ROS. Note that the balance between GSH-Px and SOD appears to be important for the cellular resistance to oxidative stress [28].

In conclusion, our results indicate that exposure to EM fields at BTS frequencies may modulate the oxidative stress of free radicals by enhancing lipid peroxidation and reducing the concentration of GSH. It is highly probable that detoxification of lipid peroxyl radicals can not be accomplished in our system. We note that reactive oxygen species may have a probable role on adverse effects of EM fields at mobile telecommunication frequencies. The outcome of this study needs confirmation by repetitive laboratory studies, including higher dose and longer duration exposure, and theoretical mechanisms underlying this effect should also be addressed in future.

THE PHYSIOLOGICAL BASIS FOR BASIC RESTRICTIONS IN EXTREMELY LOW FREQUENCY STANDARDS AND GUIDELINES

ANDREW W WOOD

HAWTHORN, VICTORIA 3122, AUSTRALIA*

Abstract

In the range 0.1 – 3,000 Hz, there are significant disparities between basic restrictions in the ICNIRP guidelines and the IEEE (ICES) standard, even though in both these are derived from consideration of abnormal retinal responses (phosphenes) and peripheral nervous system stimulation. Considerable uncertainties exist in i) interpreting the available data ii) in determining the point at which bioeffects become health effects and iii) deciding on an appropriate margin for safety for occupational and general public exposure. The available data tend to be rather sparse outside the range 20 – 60 Hz.

Recent data from large-scale voxel models and from human volunteer and modeling studies of the effects of MRI switching field gradients permit some comparisons between external fields known to cause certain bio-effects and external fields estimated from basic restriction values. Some interpolation and extrapolation across the frequency range is possible. In particular, electric field limits, which were previously thought to be entirely determined by indirect effects (contact currents and micro-shock) should now, because of results from recent voxel-based modeling, be determined more by direct effects derived from basic restrictions.

The presentation will review the approach taken by a Working Group for the development of the Australian ELF Standard

Introduction

The Australian ELF Standard Working Group, from their first meeting, faced the dilemma of whether to follow the approach of ICNIRP (ICNIRP 1998) or of IEEE (IEEE 2002) in recommending basic restrictions for protection. For example, at power frequencies and for the general public, the former approach limits induced current density (J) to 2 mA.m⁻² (averaged over 1 cm² of tissue, perpendicular to current direction) and the latter limits induced electric field (E_{int}) to different limits in different parts of the body (averaged over a 0.5 cm line segment in the body). In the most sensitive value, the brain, the 50 Hz value is 14.7 V/m. Since the two quantities can be related via $J = \sigma E_{int}$, the two approaches can be made equivalent by taking $\sigma = 0.136$ S/m, which is not too different from the average value of 0.2 S/m often used as an average value for tissue conductivity. However, because of the different assumed frequency variation, the disparities become very large at non-power frequencies. For example, the difference at 750 Hz (assuming $\sigma = 0.136$ S/m) is 15-fold (with IEEE less conservative) and at 1 Hz, 10-fold (with IEEE more conservative at these lower frequencies). This forced the Working Group to re-examine the experimental data upon which these limits (and the associated reference levels) were derived. A number of important issues emerged, as follows:

Synaptic effects in the retina

A number of experimental reports are relevant to making estimates of the threshold tissue E_{int} for a measurable physiological response to occur. Most identify 20 Hz as the frequency for the lowest threshold. Eight studies involve the application of current to the retina (electro-phosphenes) and three the application of alternating magnetic fields (magneto-phosphenes). Considerable assumptions need to be made in each case to estimate tissue threshold, which range from 1 to over 600 mV/m. Although there is a large overlap, the electro-phosphene thresholds tend to be higher than the magneto-phosphene. The pooled value (assuming the two phenomena to be equivalent) is 56 mV/m (95% CI 2.3 – 1330 mV/m). This is very close to the RMS value used as the basis of the IEEE standard.

Peripheral neural stimulation

Some recent work on human perception and of associated mathematical modelling of neural stimulation allows limits to be estimated for this phenomenon. Most of this refers to work on the fields associated with the switching of gradient fields in Magnetic Resonance Imaging, which induce currents in the body and have characteristic frequencies typically in the range 500 – 1,000 Hz. A threshold for perception of just over 2 V/m was identified by Nyenhuis (Nyenhuise et al 2001) but further analysis using more sophisticated models gives a rather higher value of around 4 V/m (So et al 2004). Other work (Liu & Crozier 2004; Liu et al 2003), tends to confirm that the threshold value for sensation is lower than the 6.15 V/m value which forms the basis for peripheral nerve stimulation in the IEEE standard (and which was derived using a mathematical model of a long, 20 µm diameter myelinated nerve).

Safety margins

There is considerable debate on the margin that should exist between the thresholds just discussed and basic restrictions for a) occupational or 'controlled environment' and b) general public categories of exposure. ICNIRP uses margins of 10, 5 or 2 depending on the context, whereas IEEE uses margins of either 1 or 3. The justifications for the actual values used are often not fully substantiated. Another area of debate is on whether the basic restriction should be related to a threshold for sensation or for harm/pain, and what the relationship between these two levels is. There is some useful information emerging on the distribution of thresholds within the general population.

Reference or Maximum Permissible Exposure Levels: relationship with Basic Restrictions

Both the IEEE and ICNIRP standards use simple homogeneous geometrical models of the human torso/head in order to derive equivalent external field limits. In recent years highly sophisticated, voxel-based, models of both the adult male and female have become available (Caputa et al 2002) (Dimbylow 2000; Dimbylow 2005; Dimbylow 1998). In addition, models of the child (Hirata et al 2001) and the pregnant female Dimbylow (Dimbylow 2006) have also been studied. Given tissue-specific Basic Restriction values, the corresponding external fields required to produce these can be found. Although most of this work is at power frequencies, other frequencies in the ELF range have also been studied (Dimbylow 2005; Dimbylow 1998). This allows reference levels to be calculated for both the avoidance of retinal and peripheral nerve stimulation effects, the latter becoming more of a concern above a few hundred Hz. For magnetic (*B*) fields reference levels can be derived fairly straightforwardly, but levels for electric (*E*) fields are a little more complicated.

Electric field limits: direct and indirect effects

Previous standards have assumed that E_{int} induced by external electric (rather than magnetic) fields are of the order of fractions of mV/m per kV/m external. Electric (*E*) field reference levels have been set to avoid indirect effects such as contact current and micro-shock. The former effectively limits *E* fields via the Deno formula (Deno 1975) since the magnitude of contact current is directly proportional to *E*. Contact current is in turn limited by considerations of annoyance thresholds for the general population. However, the voxel-based modelling studies just described predict much larger E_{int} values than previously supposed (up to 50 mV/m per kV/m in bone, for example). Consideration of E_{int} in excitable tissue gives more conservative values for external *E* than are given by the Deno formula. However, data on micro-shock still determine *E*-field reference levels for the range of frequencies less than 100 Hz (and including DC).

Giving protection below 0.1 Hz

Here, external *E*- and *B*-fields need to be considered separately: for *E*-fields the need to avoid the production of micro-shocks in DC fields gives similar reference levels to those at power frequencies. On the other hand, data on *B*-fields is much more sparse, but it would appear that the reference level at DC should be at least two orders of magnitude higher than at power frequencies.

Progress within the Australian Working Party for an ELF Standard

The Working Party has developed a draft, incorporating the considerations just outlined, which it hopes will be available for public comment before the end of the year. At power frequencies, analysis along the lines just described tend to the view that the ICNIRP *B*-field reference levels are too conservative and the *E*-field levels too lax. Other considerations include: whether in controlled circumstances or activities reference levels can be relaxed for both occupational and general public exposures; what precise tissues (and what volume) do the basic restrictions refer to; what the safety margins should be? A Regulatory Impact Statement, which will include cost-benefit analyses of a) regulatory adoption or b) voluntary compliance (with the standard as an educative document), is being prepared.

The author chairs the ELF Standard Working Group set up by the Radiation Health Committee of the Australian Radiation Protection and Nuclear Safety Agency (ARPANSA). The views presented are personal to the author and should not be taken as representing those of ARPANSA or of the Australian Government.

Abstract

The aim of the study was evaluation the effect of occupational exposure to electromagnetic fields (EMF) on the cardiovascular system.

The examinations covered all technical personnel employed at selected AM Broadcast Stations (738 -1503 kHz) - (I), radio services (150 - 170 MHz - (II), power substations (50 Hz) - (III), radio and TV broadcasting stations (VHF 30-300 MHz and UHF 0.3-3 GHz) - (IV), and Radio Link Stations (no EMF exposure) - (0). Maximum electric field strength (E_{\max}) and magnetic flux density (B_{\max}) were assessed and doses per work shift – E_{dose} and B_{dose} were calculated. 287 male workers aged 21-69, with employment duration 1- 42 years, underwent medical examination, resting and 24-h ECG, ambulatory blood pressure monitoring (ABPM). Risk of abnormalities (mostly ventricular arrhythmia) in resting and/or 24-h ECG was significantly higher for group I than for controls (OR= 6.6). In the group III, ABPM revealed a significantly higher risk of increased BP values, referred mainly to systolic BP at night-time (OR=12.5). Also in group IV, BP disturbances were significantly more frequent than in controls (OR=8.6). Cardiovascular abnormalities correlated with EMF maximum value as well as its dose. In all cases, the exposure levels were below Polish OEL values. Nevertheless, significant cardiac abnormalities, related to EMF frequency and intensity, were observed.

Introduction

The electromagnetic fields are commonly present both in the communal and work environments. The potential hazard they may pose to human health is a matter of dispute among scientists. The external electric and magnetic fields have a theoretical potential to affect the functions of different body systems through generating electric impulses within them. Most sensitive to EMF influence are the cardiovascular and nervous systems, particularly the autonomic nervous system responsible, among others, for neurovegetative regulation of the cardiovascular function. The experimental studies conducted thus far indicate that EMF within radio-, microwave and power frequencies can produce measurable biological effects. However, there is no simple relation between the biological and health effects. The biological effects detected at the cell or tissue level may not, and most often do not, translate into overt health effects, owing to the adaptation and repair mechanisms of the living organisms. Moreover, the findings of experimental animal studies can hardly be extrapolated to humans in view of the anatomic and functional differences between species.

Therefore, for evaluating health effects of EMF exposure, the most significant are experimental, clinical or epidemiological studies on humans. The experimental studies make it possible to assess immediate response but not the delayed effects. Consequently, they are of little use for the assessment of effects of occupational exposure that may last several years. Much more valuable are the clinical studies. However, these have been rather scarce so far. Although there are quite a few reports on such studies conducted in the former Soviet Union, they have been commonly criticized for several methodological drawbacks and deficiencies, including ad hoc selection of the study population, lack of control group, lack of accurate assessment of electromagnetic environment, and lack of adjustment for the confounding factors [1]. Further, the methods applied may not have been relevant to the study objectives. To assess the cardiovascular function, the authors most frequently used resting ECG and office BP measurements which are inadequate for detecting functional impairments or early subclinical signs of cardiac dysfunction.

Epidemiological studies can provide the best evidence on the possible health effects of EMF exposure. The studies performed thus far were intended mostly for the assessment of cancer risk from EMF exposure. The results of the first epidemiological study concerning the cardiovascular system were published in 1999. Savitz et al. [2] examined the mortality from cardiovascular diseases in relation to occupational exposure to 50 Hz EMF in a cohort of 138 903 male electric utility workers from five US companies over the period of 1950-88. Age-, race-, and social class-adjusted long-lasting exposure to high level EMF was associated with an increased risk of

death from arrhythmia-related conditions: (n=212) SMR=1.11-2.04 and acute myocardial infarction: (n=4238) SMR=1.07-1.66. These data suggest a possible association between occupational EMF exposure and arrhythmia-related heart disease.

Few epidemiological studies on non-carcinogenic effects of radio frequency and microwave EMF exposures have been published. It was only the questionnaire studies on subjective complaints among mobile phone users and physiotherapists [3-5].

Since 1993, in Nofer Institute of Occupational Medicine, has been conducting comprehensive studies on the neurovegetative regulation of the cardiovascular function in workers exposed to different frequency EMFs [6-9]. The aim of these studies is to investigate the influence of EMF exposure on the cardiac function and find out whether and to what extent the EMF frequency and exposure level can determine the type of cardiovascular abnormalities and neurovegetative function affected.

Methods

For the study, the non-invasive methods of 24-h ECG (Holter) and blood pressure monitoring (ABPM) have been applied which are useful for the examinations of healthy individuals during their normal professional and daily activities. These methods are helpful in detecting not only the clinical manifestations of the disease, but also in early diagnostics of a dysfunction of the cardiovascular system. The examinations were carried out in compliance with the standards of the International Society for Holter and Noninvasive Electrocadiology [10]. The protocol was approved by the Regional Biomedical Ethics Committee.

In all workers the following examination were performed:

- *anamnesis*, with an interview on the risk factors of cardiovascular diseases: family history of metabolic and cardiovascular diseases, lifestyle, nutritional habits and physical activity,
- *routine physical examination*, with office blood pressure measurement (according to WHO guidelines),
- *routine ECG* during rest in the supine position, using Medea system (Gliwice, Poland) from 12 typical leads. The results obtained were evaluated based on generally adopted standards,
- *24 h ECG monitoring* on normal workday, using Medilog Suprima (Oxford, England) set from three bipolar leads. This method is thought to ensure the most accurate diagnostics of cardiac rhythm disturbances, conduction impairments and ischemia, especially silent ischemia. Final results, including heart rate, symptoms of ischemia, arrhythmia and conduction disturbances were related to the international standards for Holter ECG [10],
- *Blood pressure monitoring (ABPM)* - 24-h ambulatory blood pressure monitoring was performed during everyday professional and other activities using DX-Medilog Systems. The measurements were carried out automatically, every half hour during daily activities and every hour during sleep. Mean, systolic (BPS) and diastolic (BPD) blood pressure and heart rate (HR) for 24 hours (O), day-time activity (D) and night-time rest (N) were calculated and related to the Staessen's standards of arterial blood pressure as the reference values [11]. The day-night ratios were determined for systolic and diastolic blood pressure (BPSD/BPSN, BPDD/BPDN). Subjects with BP ratio lower than 1.1 are called the 'non-deepers' (subjects without a physiological nocturnal decrease in systolic and/or diastolic blood pressure).
- *Exposure evaluation*: To assess the worker's individual exposure to EMF, the following parameters were measured:
 - I. in workers at AM broadcasting stations: maximum value of electric field strength (E_{max}) and dose per workshift (E_{Dose}),
 - II. in workers of radioservices, who were periodically exposed to EMF emitted by the repaired equipment only (E_{max}) were measured, because it was impossible to calculate (E_{Dose}),
 - III. in workers at substations: maximum value of electric field strength (E_{max}), maximum value of magnetic flux density (B_{max}) and doses per workshift - E_{Dose} and B_{Dose} ,
 - IV. in workers at broadcasting stations: maximum value electric field strength (E_{max}), mean value of E (E_{mean}) and lifetime dose of E (E_{dose}) separately for VHF, UHF and VHF+UHF. Our assessment of exposure was based on the spectrum analysis of a typical station broadcasting in UHF and VHF bands and on the specifications of the apparatus installed there.

The EMF dose was determined using quasi-dosimetric method. The following procedures had to be completed prior to final exposure assessment:

1. Assessment of the average time the workers spent in particular functional units of the object within a workshift. This was based on an interview and work timing of each worker.
2. Calculation of the mean intensity of electric and magnetic field (if it was measureable) This was done by carrying measurements in several-several dozen locations all over each unit where the workers were

CARDIOVASCULAR FUNCTION IN WORKERS EXPOSED TO EMF

staying. The results of these partial measurements were then averaged for the whole area of the unit. In each of such areas, the maximum values were recorded of electric and magnetic field intensities that the workers had been exposed to.

3. For exposure assessment, the highest of the maximum value of EMF and the total E and H doses per workshift were considered. Lifetime dose was calculated for each worker from the history of employment and job timetable.

For electric field intensity measurement, the HOLADAY Ind. (USA) measuring set and broad-band MEH-1a meter (Technical University, Wrocław, Poland) were applied

For measurements of magnetic field intensity, the MNP89 meter (Technical University of Wrocław, Poland) was applied.

Subjects

The groups under study consisted of technical personnel and security service workers who were qualified by the occupational health practitioners as capable for work at permissible EMF levels. The subjects were randomly selected from the total number of such stations in Poland. All workers at each appointed station were examined. All subjects from the exposed and control groups gave their formal consent prior to inclusion in the study. Before the onset of the examinations, all the procedures were explained in detail to each participant.

The examinations were carried out in:

- AM broadcasting stations - exposed group I. The AM stations selected for the study operate at frequencies ranging from 738 kHz to 1503 kHz. These objects can be characterized by permanent exposure of their workers to electromagnetic fields (mostly electric). The main source of EM fields in the AM stations are the transmitting antennas (half-wave dipole), radio transmitters and feeders (which conduct radio signals from the transmitter to the antenna),
- Radio-services - exposed group II. Mobile radio-communication network requires permanent technical supervision by radio-service units. During the service operations, undesirable EM fields are generated by unscreened transmitters, improper tuning instruments and transmitting-receiving antennas installed in the service-rooms. The radio-service workers under study were exposed to EM fields with frequency varying from 150 to 170 MHz,
- Substations - exposed group III. Substations are the element of a power system, in which electric power is distributed and/or transformed. The substations under study work at high and extra high voltage (110 kV-400 kV). The substation equipment is a source of 50 Hz electric and magnetic field, Broadcasting stations that operate at frequencies ranging from 66 MHz to 727 MHz – exposed group IV, The operators of radio- and TV stations are exposed to different EMF levels, depending on various factors such as transmitter technological characteristics, feeder quality, distance from the antenna, etc. These factors differ considerably between the individual broadcast stations. Radio Link Stations - the control group (0). Radio Link Stations are the elements of a telecommunication system in which signals are transmitted using EM waves focused into very row beams by directional (mostly parabolic) antennas. As the antennas are installed in highly inaccessible locations and the radiation beams run high above the ground, the workers of the Radio Link Stations are free from being exposed.

Table 1. Characteristics of the study population

	Exposed groups				Control group
	AM Broadcasting Stations (I)	Radioservices (II)	Substations (III)	Broadcasting stations (IV)	Radio Link Stations (0)
Number of subjects	71	40	63	71	42
Age (years)	46.9±13.1*	36.9±11.5	39.0±10.0	45.3±9.4	40.7±2.2
Employment (years)	18.6±12.1	12.5±9.5	15.0±10.0	19.1±8.8	17±13
Diseases diagnosed:					
hypertension	12 (17%)	6 (15%)	11 (17%)	11 (15%)	8 (19%)
diabetes, type II	1	0	0	1	1
Subjective symptoms	31 (44%)	26 (65%)	30 (46%)	36 (51%)	15 (29%)
BMI	26.0±3.0	25.0±3.0	26.0±4.0	26.9±3.8	25.4±4.0
No. of smokers (more than 10 cigarettes/day)	33 (47%)*	15 (37.5%)	21 (33%)	17 (24%)	17 (40%)

BMI (body mass index) = body mass/height² (kg/m²)

* statistically significant difference (p≤0.05)

The exposed groups were similar with respect to the level of leisure time physical activity, and dietary and smoking habits. They differed only with regard to the age. The possible influence of this difference on the study results was eliminated using statistical methods.

Results

In all the exposed groups, the assessment of EMF exposure revealed levels not higher than those attributed to the hazard area according to Polish OEL values.

Table 2. EMF exposure in the study groups

Groups	Exposed				Non-exposed Radio Link Stations (0)
	AM Broadcast Stations (I)	Radio-services (II)	Substations (III)	Broadcasting stations (IV)	
EMF frequency	738-1503 kHz	150-170 MHz	50 Hz	66-727 MHz	0
E_{\max}	50-550 [V/m]	2-55 [V/m]	4.3-6.7 [kV/m]	7.9-16.7 [V/m]	0
B_{\max}	negligible	negligible	26.1-37.3 [mT]	negligible	0
E_{dose}	50-260 [(V/m)h]	irregular exposure	0.2-15.2 [(kV/m)h]	50-260 [(V/m)h]	0
B_{dose}	negligible	negligible	1.4-38.9 [mTh]	negligible	0

Our studies did not reveal any significant differences between the exposed and non-exposed groups with respect to the frequency of abnormalities in resting ECG. Significant differences between group (I) and other groups, were found in Holter 24-h ECG and when the resting and Holter ECGs were regarded as complementary (table 3) In group (II-IV) the abnormalities in 24-h and/or resting ECG were more frequent than in non-exposed group, but the differences were insignificant. In group (I) among the abnormalities in Holter ECG records dominated the ventricular heart rhythm disturbances, in others repolarization impairments. In switch-yard substation workers (group III) exposed to high and extremely high voltages ranging from 110 kV to 400 kV blood pressure changes prevailed among the recorded cardiovascular impairments and were significantly more frequent in the exposed group than in controls (table 3). The ambulatory blood pressure monitoring revealed an increased frequency of subjects with elevated BP in substation workers (38%), and Broadcasting Stations workers (32%) as compared with the non-exposed subjects (23%).

Table 3. Percentage of subjects with ECG and blood pressure abnormalities

Groups	A: resting ECG	B: Holter monitoring	A and/or B	ABPM	Office BP
AM broadcasting stations (I)	34	56	83	6	20
Radioservices (II)	30	32.5	55	20	22.5
Substations (III)	29	40	48	38	19
Broadcasting stations (IV)	34	44	59	70	34
Radio Link Stations (0)	26	31	40	23	19
p	ns	I vs. 0 (p=0.02)	I vs. 0 (p=0.001)	III vs. 0, IV vs. 0 (p=0.04)	ns

In group (III) and (IV) the mean systolic blood pressure for 24 hours, day-time activity and night-time rest were significantly higher than in the controls. Mean values of diastolic blood pressure for 24 hours (24-h) and night-time rest were significantly higher in the group IV (Fig. 1). In groups I and II in comparison with control group it has been found that mean blood pressure, both 24-h and that recorded during daytime and at night, did not show statistically significant differences. Only the diastolic blood pressure recorded during the night hours was higher in group I, II and IV than in the control, but the difference was on the border of the statistical significance ($p = 0.0512$).

Number of non-dippers was significantly higher in group I (37%) and III (48%) and IV (61%) in comparison with control group (23%) and group II (28%). HRD was found to be significantly lower in the groups I and III than in the

control group, despite the fact that physical and mental load during work and leisure time were similar. HRD/HRN was significantly lower in the groups I, II and III than in the control group. The decreased value of this parameter may indicate a dysfunction of the neurovegetative regulation.

In the group IV it was a significantly higher percentage of subjects with impaired BP regulation, expressed as the absence of physiological nocturnal systolic and diastolic BP drop.

Fig. 1. Blood pressure in the study groups (ABPM results)

The risk analysis revealed that the probability (odds ratio) of abnormalities in resting and/or 24h ECG was 6.6 for group I, 2.0 for group II, 1.4 for group III and 4.5 for group IV, as compared with the control group. On the other hand, the ABPM monitoring revealed that when compared to the values found for controls, the risk of elevated blood pressure was lower in group I, comparable in group II, and significantly higher in group III and IV. The increased BP values referred mainly to systolic pressure at night (odds ratio=12.5). In group IV, the risk of elevated arterial blood pressure was 8.6.

Relationship between cardiovascular disturbances and parameters characterizing the level of exposure.

The disturbances in ECG and blood pressure regulation were dependent on EMF exposure level. In group I, a significant relationship was found between mean BPSN and E_{dose} ($p=0.004$) as well as between BPSN and E_{max} ($p=0.03$). In group II, the relationship between BP level and exposure parameters was not analysed. Such an analysis could not be performed due to the specific job characteristics in this group - the workers were periodically exposed to EMF emitted by the repaired equipment and it was impossible to determine the level of their exposure. In group III, BP disturbances significantly correlated with exposure parameters. BPDO, BPDD, and BPDN were found to depend on the period of employment ($p=0.023$, $p=0.05$, $p=0.001$ respectively). A significant correlation was found between BPSN and BPDN and the maximum values of electric and magnetic fields ($p=0.043$ and $p=0.026$). In group IV, the disturbances in blood pressure regulation were dependent on EMF

exposure parameters. The risk of BP changes increased with higher lifetime dose in the UHF-VHF bands ($OR=2.3$) as well as higher E_{mean} in the UHF and VHF bands ($OR=2.3$, $OR=2.5$, respectively). The risk of impaired BP regulation (no nocturnal blood pressure drop) significantly increased with lifetime dose in the UHF range ($OR=2.6$) and with a growing E_{mean} in the VHF range ($OR=2.1$).

Summary

Although the occupational exposure limits, as laid down in respective Polish regulations, were not exceeded, the different impairments in circulatory system were observed in exposed workers. In workers at AM broadcasting stations, heart rhythm disturbances, detected by 24-h ECG monitoring, were more frequent than in the non-exposed workers as well as workers exposed to 50 Hz EMF. On the other hand, in workers at substations and broadcasting stations, an increased frequency of elevated BP (detected with ABPM) was found, compared with other groups. Our results suggest that the frequency of EMF determines the type of the observed cardiovascular disturbances.

Significant BP disturbances occurred mainly at night; therefore, the office BP measurement is inadequate to detect them. It is also worth noting that in EMF-exposed workers, increased BP levels in ABPM could be found both in the persons showing normal and increased BP values in a single office measurement. Therefore, the present scope of prophylactic examinations seems to be inadequate for workers occupationally exposed to EMF and it should be extended with 24h monitoring of the ECG and blood pressure.

Abstract

The external electric and magnetic fields have been evaluated near a 132 kV transmission line, where members of the general public are likely to be exposed. A double circuit existing transmission line is used for the assessment. The fields have been generated using EPRI's EMF workstation software. The field calculations are based on the charge simulation method for the electric field, and Biot-Savart law for the magnetic field. The predicted electric field at the right of way was found to be 0.165 kV/m and the magnetic field was 21.4 mGauss. The results are presented in the form of field profiles at ground level around one span for both sides of the transmission line, and up to 250 ft. from the centre of the transmission line. The results for both the electric and magnetic fields have been compared with the international standards for the maximum allowable level. The comparison shows that members of the general public are exposed to field levels below those set by the standards.

Introduction

Exposure of the general public to electric and magnetic fields resulting from high voltage power transmission lines has been of prime concern for many years among electric power establishments as well as the general public. Field assessment and epidemiological studies drew a lot of attention to this during the past few decades. The aim of these studies has been to establish the safe exposure levels to power frequency electric and magnetic fields for the general public as well as line workers. Limited knowledge and information available regarding the general public exposure to these fields tends to magnify intensively the risk of exposure to extremely low frequency fields. The SEC transmission networks above 110 kV spans a total length of 33,685 circuit-km (ckm). This consists of 7,490 ckm for 110 – 115 kV, 14,451 ckm for 132 kV, 3,850 ckm for 230 kV and 7,894 ckm for 380 kV of transmission networks [1]. These figures indicate the proximity of high voltage transmission lines and locations of residential areas occupied by the general public. They also justify the need for the assessment of the electric and magnetic fields at and beyond the right of way (ROW) of the high voltage transmission lines.

There has been rising interest over the years in determining the safe exposure levels of people, mainly workers, and the general public, to power frequency electric and magnetic fields [2]-[8]. Several organizations have developed standards and guidelines for such permissible exposure levels. By far, the most important organizations that have contributed to the establishment of these standards and guidelines are the Institute of Electronic and Electrical Engineers (IEEE) [2], and the International Commission on Non-Ionizing Radiation Protection (ICNIRP) [3]. There are other organizations such as the American Conference of Governmental Industrial Hygienists (ACGIH) [4], and the National Radiological Protection Board (NRPB) that have made a major contribution [5],[6]. There are many government agencies and organizations that have published articles on this subject [7],[8].

The permissible levels quoted in many countries refer to the permissible levels set by the IEEE standard, and the ICNIRP guideline. Table 1 lists a summary of the external exposure limits for 60 Hz for the IEEE, ICNIRP, NRPB, and ACGIH for the general public.

TABLE 1
SUMMARY OF EXTERNAL EXPOSURE LIMITS FOR THE GENERAL PUBLIC.

Organization	E (kV/m)	$B \times 10^4$ (mG)
IEEE	5	0.833
ICNIRP	4.2	0.1
NRPB	12	1.3
ACGIH	No specific standard for general public.	

This paper presents an exposure assessment study for the general public exposed to a practical double circuit HV transmission line. The selected line spans from substation 8114 (Qortoba Area) to substation 8079 (Alhamra Area-Khorais) in the Riyadh region of Saudi Arabia. Its nominal voltage and power ratings are 132 kV and 293 MVA respectively. This paper introduces detailed system data after this introduction. A description of the charge simulation method and Biot-Savart law used in the evaluation of the electric and magnetic fields follow the data section. The results of the external fields, with emphasis on the right of way and beyond are then presented. The following section introduces a comparison between the evaluated fields and the standards set by the IEEE, ICNIRP, ACGIH, and the limits recognized and used by several countries all over the world. The paper terminates with a conclusion, acknowledgment, and references.

System Data

A real double circuit transmission line is selected by SEC for the study of the exposure to electric and magnetic fields. The selected line spans from substation 8114 (Qortoba Area) to substation 8079 (Alhamra Area-Khorais) in Riyadh region. The nominal voltage and power ratings are 132 kV and 293 MVA respectively. Detailed line data and tower dimension are presented in Fig.1. and line details is delineated in Table 2.

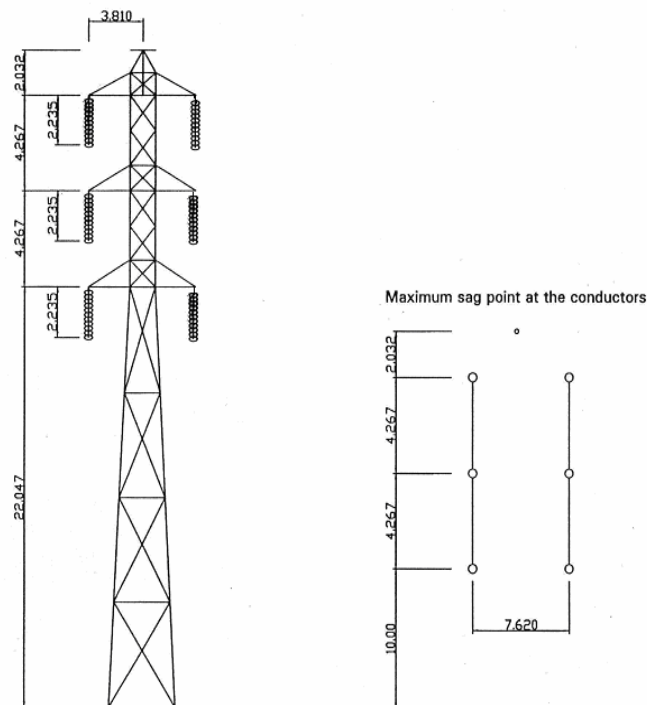

Fig. 1. Tower dimension for the 132 kV transmission line.

TABLE 2
TRANSMISSION LINE DATA FOR THE 132 kV LINE.

Line Ratings		
Rating (MVA)	293 MVA	
Nominal Line Voltage (kVL-L)	132 kV	
Actual Line Voltage (kVL-L)	132 kV	
Nominal Line Current (kA)	1.284 kA	
Peak Load Current (kA), for Both Circuits	Circuit 1	Circuit 2
	603 A	603 A
Line Conductor And Overhead Ground Wire Parameters		
Conductor/Ground Wire	Conductor	Ground Wire
Diameter (cm)	2.773 cm	1.03 cm
Number of Sub-conductors	SINGLE	
Phase Relation of Conductors	VERTICAL (R-Y-B)	
Right of Way	40 m	
Full span (m)	305 m	
Mid Span height (m) or Sag (m) (lowest point)	10 m	

The external field evaluation has been carried out at ground level and for distances up to ± 250 ft from the centre of the transmission line. This range encompasses the right of way of the transmission line and beyond and gives a good indication of the level of exposure of the general public to the electric and magnetic fields resulting from the near by transmission line. Similar results concerning line workers have been reported in [15].

External Electric and Magnetic Field Calculations

The basic physics of quasi-static fields allow separate discussion of power frequency electric and magnetic fields [9]. The solution methodology for both the electric and magnetic fields are highlighted in this section.

A. Charge Simulation Method

The solution methodology for electric field is based on the two-dimensional charge simulation method. This commonly used approach consists essentially of two stages: (1) calculation of the equivalent charges per unit length of conductor and (2) calculation of the electric field produced by these charges. A detailed treatment of the calculations is given in [10]-[13] and summarized here. The general relationship used to calculate the charges on a multi conductor system is presented in matrix form in (1).

$$[Q] = [P]^{-1} [V] \quad (1)$$

Where: $[Q]$ is a column vector of the linear charge on each conductor; $[V]$ is a column vector of the potentials of the conductors; $[P]^{-1}$ is the inverted matrix of the Maxwell potential coefficients of the conductors. A set of image conductors is used with charges opposite to those of the transmission line. The actual conductors and their images are characterized by real and imaginary voltages and diameters. Overhead shield wires are also included in this method (and assumed to be at zero potential). For bundled conductors, a single conductor with an equivalent diameter is used, on the basis of the following formula:

$$d_{eq} = D \sqrt[n]{\frac{nd}{D}} \quad (2)$$

where

d_{eq} is equivalent single conductor diameter; n is number of sub conductors; d is diameter of individual sub conductor ; D is geometric diameter of the bundle. The self and mutual Maxwell potential coefficients are calculated for the conductor system on the basis of line geometry and conductor diameter using the following equations.

Self:

$$P_{ii} = \frac{1}{2\pi\epsilon} \ln \left(\frac{2y_i}{d_i} \right) \quad (3)$$

Mutual:

$$P_{ij} = \frac{1}{2\pi\epsilon} \ln \left(\frac{(x_i - x_j)^2 + (y_i + y_j)^2}{(x_i - x_j)^2 + (y_i - y_j)^2} \right)^{1/2} \quad (4)$$

where

$\epsilon = 8.85 * 10^{-12} \text{ F/m}$ (Dielectric constant of air); d_i is conductor diameter or equivalent bundle diameter of conductor i ; y_i, y_j = heights of conductors i and j above ground; x_i, x_j = horizontal coordinates of conductors i and j with respect to a reference. The inverted potential coefficient matrix $[P]^{-1}$ is multiplied by the column matrix of line-ground conductor voltages to yield the charges per unit length of the conductor, as shown in (1). These charges are then used to calculate the real and imaginary parts of the horizontal and vertical components of the electric field [13].

B. BIOT-SAVART Law

The basic equation for calculating the magnetic field of a long, straight wire is derived from Ampere's Law [11,14] and given in (5):

$$H = \frac{i}{2\pi r} \quad (5)$$

Where: H is the magnetic field intensity (A/m); i is the electric current in the wire (Amperes); r is the distance between the wire and the point of interest (meters)

The fundamental unit for the magnetic field intensity, H , is the Ampere per meter (A/m). However, magnetic field exposure technology often uses the magnetic flux density, B . The relationship between H and B is given by

$$B = \mu H \quad (6)$$

where: B is the magnetic flux density (Gauss); μ = Permeability constant used for both air and ground ($4\pi * 10^{-7}$ Henry/m)

The magnetic field is a vector field with both vertical and horizontal components. The field, as computed in Eq. 6, is separated into vertical and horizontal components by multiplying by $\sin(\theta)$ and $\cos(\theta)$. In general, both components must be retained. For three-phase ac fields, the vertical and horizontal components must be combined individually as phasors, regarding the angles of the different currents. The total magnetic field is the sum of all the contributions from the line currents as given in (7).

$$B_{i,j} = \sum \left[\frac{\mu I_i}{(2\pi r_{i,j})} \right] \varphi_{i,j} * 10^4 \quad (7)$$

Where: $r_{i,j}$ is the distance between point and conductors and $\varphi_{i,j}$ is the unit vector in the vector cross-product direction of the current vector and the vector segment $r_{i,j}$. For a three phase ac transmission line, the field at any point can be described by the field ellipse (similar to the electric field).

Evaluation of the External Electric & Magnetic Fields

In this study the electric and magnetic fields produced by the transmission line at ground level, have been modelled using the subroutine EXPOCALC of the EPRI's software EMF Workstation, Version 2.51 [14]. The software package used, starts by setting the general required parameters such as the designated area of concern parameters, the structure position, boundary area, as well as the field calculation height. The line design parameters are entered in a detailed manner and that includes phase structure of the line, conductor size, applied voltage and the operating current. The span specifications are then taken into consideration.
